Introduction

Anti-bacterial agents are divided into disinfectants and antibiotics. Disinfectants are not used as medicines, but are part of the formulation of products such household cleaners, soaps, detergents, health and skincare products, etc. Examples of commonly used disinfectants are quaternary ammonium compounds, chlorine, triclosan, metallic salts, etc. In contrast, antibiotics are animal or human drugs that specifically either kill (bactericide) or inhibit the growth of bacteria (bacteriostatic).

In general, antibiotics target essential processes such as cell wall synthesis, protein synthesis, nucleic acid synthesis, tetrahydrofolate synthesis, etc. in metabolically active bacteria.

Since their discovery, antibiotics have been very effective in resolving bacterial infections in humans and animals, and therefore have contributed to the achievement of a higher quality of life and longer life span. Antibiotics are very specific for bacterial processes, and so can be administered at high doses without having severe side effects. Nevertheless, they also have some limitations, such as being less effective to eradicate biofilm embedded bacteria and persister cells (since they are dormant and hence impervious to the inhibition of metabolic processes). Additionally, antibiotics also affect commensal and mutualist microbiota and can promote dysbiosis and colonization or proliferation of potentially harmful bacteria, such as *Clostridioides difficile*, which causes chronic diarrhea.

Antibiotic resistance appears when bacteria previously sensitive to antibiotics change in ways that reduce or eliminate their effectiveness. These changes are due to bacterial evolution, horizontal gene transfer, and by mutations, and therefore threaten the single greatest therapeutic advance in the history of medicine (Bankevich et al., 2012). Antibiotic resistance is achieved by changes in the phenotypic and/or genotypic characteristics of bacteria, and can be classified according to its origin and mechanisms (Davison et al., 2000). Antibiotic resistance is an increasing threat for humankind since it increases mortality rates and the length of hospital stays for people infected with multi-drug-resistant (MDR) bacteria (Heffernan et al., 2018). Extensive use of antimicrobial agents in hospital settings and in animal husbandry, has led to the emergence of pan-resistant “superbugs” (Meir-Gruber et al., 2016).

Among the most problematic bacteria are *Staphylococcus aureus* resistant to methicillin (MRSA), vancomycin-resistant enterococci (VRE), *Klebsiella pneumoniae*, *Acinetobacter baumannii* and members of the genus *Pseudomonas* and *Salmonella* (Baumann et al., 2017). All these bacteria are ESKAPE pathogens, which are very difficult to treat due their low sensitivity towards most antibiotics and cause high mortality and increased health care costs.

The World Health Organization (WHO) included the ESKAPE pathogens for the development of new antibiotics (12 bacteria were chosen as a priority) (Mulani et al., 2019). To generate effective tools for combating the ESKAPE pathogens, it is necessary to increase our understanding of their resistant mechanisms, their virulence, and their transmissibility, to improve strategies of combat. Focusing on the most resistant and virulent bacteria could help to mitigate the damage caused by the antimicrobial resistance (AMR) and will allow a more efficient evaluation of novel antimicrobial agents (Pendleton et al., 2013). The urgent need for the generation of novel, effective antimicrobials must be taken into account by pharmaceutical research and development in order to avoid the beginning of the post-antibiotic era (Tacconelli et al., 2018).

In this article, the main, currently used antibiotics, their targets, their mechanisms of action, their spectrum, their uses, and known-resistant mechanisms, are explained.

Antibiotics that disrupt cell walls

Beta-lactams

Beta-lactam antibiotics represent the largest family of antimicrobials and have a natural or semi-synthetic origin and are considered broad spectrum antibiotics. They are characterized by the presence of a heterocyclic beta-lactam ring that is structured by a heterocyclic ring of three carbon atoms and one of nitrogen, with the characteristic of having complementary side chains related to their antimicrobial activity, pharmacokinetics and toxicity (Barcelona et al., 2008). Their mechanism of action is based on the inhibition of the last stage of the synthesis of the bacterial cell wall, inhibiting peptidoglycan synthesis by blocking the transpeptidation or by activation of the bacterial autolysin that destroys the peptidoglycan. However, for a beta-lactam to be activated, it will need to be anchored to other radicals usually other rings; hence, in order to act, they must bind to proteins of the bacterial wall called PBPs (penicillin binding proteins) (Gualerzi et al., 2013). The main mechanism of resistance against β -lactams that occurs in Gram-negative bacteria, involves β -lactamases (periplasmic enzymes that hydrolyze the β -lactam ring) and β -lactamases (that confer resistance to cefotaxime, ceftazidime and aztreonam) are called "extended spectrum β -lactamases" and are often encoded in transposons and located in self-transferable plasmids that have promoted the spread of antibiotic resistance among bacteria globally (Worthington and Melander, 2013).

Penicillin

Penicillin can be of natural or semisynthetic origin, conformed by a structure of a beta-lactam ring, 6-aminopenicillanic nucleoside joined to a thiazolidine ring. Its bacterial spectrum includes Gram-positive and negative cocci and Gram-positive rods, facultative anaerobes, spirochetes, and some Gram-negative anaerobic rods (Miller, 2002). Penicillins are bactericidal in adequate doses and bacteriostatic in low concentrations. The binding of the beta-lactam ring of penicillins with DD-transpeptidase (mostly present in Gram-negative bacteria) prevents the formation of the cell wall, causing the bacterial lyses. The effectiveness of penicillin depends in its affinity to the PBPs. Penicillin is generally used in dental infections, pneumococci, endocarditis (*Streptococcus viridans*), meningococcal meningitis, gonorrhea (*Neisseria gonorrhoeae*) while not producing penicillinase, syphilis, diphtheria, tetanus, surgical prophylaxis, etc. (Miller, 2002).

The mechanisms of resistance to penicillin are mediated by the *blaZ* gene that codes for a beta-lactamase which hydrolyzes penicillin to produce inactive penicilloic acid. *S. aureus*, *Haemophilus influenzae*, gonococcus, and most Gram-negative enteric bacilli produce inducible beta-lactamases or penicillinases, while Gram-positive bacteria produce β -lactamases in varying amounts. The genetic control of the β -lactamases resides in plasmids that are transmissible to other bacteria by bacteriophages. On other occasions, resistance may be intrinsic, due to mutation and generation of mutant beta-lactamase-producing strains (Corsini Campioli et al., 2021).

The origin of amino penicillins lies in ampicillin, discovered in 1961. Amoxicillin differs from ampicillin by the addition of a hydroxyl group; it is chemically like penicillin and derived from I, but has greater gastrointestinal absorption than ampicillin, with a wider spectrum. Amoxicillin is bactericidal, although it is prone to be degraded by beta-lactamases (Miller, 2002). The mechanism of action of amoxicillin consists of binding to specific PBPs, inhibiting transpeptidation, causing the activation of autolytic enzymes in the cell wall, leading to bactericidal lysis. It can also be combined with a beta-lactamase inhibitor, such as clavulanic acid and sulbactam. Amoxicillin is used as a treatment for genitourinary tract infections, ear, nose and throat infections, *Helicobacter pylori* infections, rhinosinusitis, pneumonia, pharyngitis, tonsillitis, and skin infections. The known resistance mechanisms for amoxicillin consist of inactivation by beta-lactamases that are not inhibited by clavulanic acid, including classes B, C and D, as well as alterations of PBP proteins (Miller, 2002).

The anti-staphylococcal penicillins also known as isoxazolylpenicillins (Oxacillin, cloxacillin, dicloxacillin and flucloxacillin) are resistant to beta-lactamases, penicillinases and gastric acids. They are used mainly for infections generated by *Streptococcus pneumoniae*, group A streptococci and *Staphylococcus epidermidis*, and are used for uncomplicated skin diseases (folliculitis, furunculosis and cellulitis) (Miller, 2002).

Piperacillin also belongs to this group and is used for infections including those of the urinary tract, intra-abdominal, and of the skin and soft tissues, such as for diabetic feet and pneumonia. In combination with an aminoglycosides. Piperacillin is synergistic for treatments against *Pseudomonas*. It is not absorbed orally, but intravenously or intramuscularly. It is also used in streptococcal and enterococcal infections and has variable activity against *E. coli* and *Klebsiella*. The main resistance mechanisms are efflux pumps and alterations in the porins (Yang et al., 2015).

Cephalosporins

The first cephalosporins were obtained from the *Cephalosporium acremonium* fungus. Later on, modifications of their side chains had produced different generations. The cephem nucleus (chemical base of cephalosporins) is hydrophilic and capable of spontaneously crossing membranes, including those of the digestive epithelium, which is why they are administered parenterally. Its mechanism of action consists mainly in blocking the incorporation of peptidoglycan (El-Shaboury et al., 2007). Cephalosporins have broad spectrum activity against enterococci, *Listeria monocytogenes*, and cloxacillin-resistant staphylococci. Cephalosporins are undoubtedly the most recommended β -lactams due to their stability against β -lactamase enzymes. They are used as a treatment for respiratory, skin and urinary tract infections (El-Shaboury et al., 2007). First-generation cephalosporins have a spectrum of action similar to that of penicillin. Administration is oral and parenteral, as is the case of cefazolin. They are used for infections of the skin, bones, joints, genitals, blood, heart valve, respiratory tract (including pneumonia), biliary tract, and urinary tract. Cephalothin is one of the most resistant cephalosporins against β -lactamases, inhibits transpeptidases, has bactericidal activity and is efficient for urinary tract, gynecological, cardiac, and gastrointestinal infections. First-generation cephalosporins are used in surgical prophylaxis. Resistance to cephalothin arises when PBP transpeptidases are modified (Shahbaz, 2017).

Second generation cephalosporins, are more active against Gram-negative enterobacteria than first generation ones, as they are active against Gram-negative and Gram-positive cocci, but not against *Pseudomonas*, *Klebsiella* and some *Proteus* strains. Cefuroxime is bactericidal, its spectrum is similar to that of cefamandole, but it is more resistant to hydrolysis by β -lactamases; it penetrates in sufficient quantities in the cerebrospinal fluid. It is used as a treatment for meningitis (pneumococcal, meningococcal, by *H. influenzae* and by *S. aureus*), in infections of the lower respiratory tract and in the prophylaxis of chest surgery (Shahbaz, 2017). Cefoxitin has a broad spectrum against indole producing *Proteus* and *Serratia* sp., active against anaerobic Gram-negative bacilli and *B. fragilis*. It is used mainly for mixed anaerobic infections (peritonitis and diverticulitis), prophylaxis after colorectal operations, vaginal/abdominal hysterectomy and appendectomy and for infections of the respiratory, urinary and genital tract, abdomen, blood (septicemia), bones and joints, skin and soft tissues, burns or infected wounds, and prophylaxis.

Both (cefuroxime and cefoxitin) can be used to treat sinusitis and otitis media in patients who do not respond to amoxicillin (Brumfitt et al., 1974). Third generation cephalosporins are characterized by having 2-aminothiazolyl ring as a side chain, and they have broad spectrum activity against most Gram-negative, including those producers of β -lactamase. Third-generation cephalosporins are used in infections caused by Gram-negative bacilli, unusual hospital infections by Enterobacteriaceae, infections in immunosuppressed patients, pneumonia, urosepsis, meningitis and intra-abdominal, uncomplicated gonorrhea, osteomyelitis, infections of the skin and soft tissues and in Lyme Disease, etc. (Bennett et al., 2014). Ceftazidime inhibits the third and final stage of bacterial cell wall synthesis by preferentially binding to specific PBPs, it is active against *P. aeruginosa*, but less active than other third generation agents against Gram-positive cocci. It is structurally related to cefoperazone, but is less effective than moxalactam, cefotaxime, ceftizoxime, and ceftriaxone against Enterobacteriaceae. It is used in nosocomial infections due to Gram-negative, meningitis (combined with aminoglycosides if *Pseudomonas* is suspected) and in the treatment of febrile neutropenic patients (Bennett et al., 2014).

Ceftriaxone has an aminothiazolylacetyl group and a side chain at position 7 of a methoximino group, which generates an increase in antibacterial activity against Enterobacteriaceae. Its spectrum includes *Enterobacter*, *Citrobacter*, *Morganella*, *Providencia*, *Moraxella catarrhalis*, *Neisseria meningitidis*, *H. influenzae* and *N. gonorrhoeae* and the drug of choice for the treatment of gonococcal infections it is also used against central nervous system infections, middle ear, peritonitis, urinary tract, kidneys, bones, joints, skin, etc. (Harris et al., 2018).

Cephalosporins belonging to the fourth generation are characterized by the presence of a methoxy-imino aminothiazolyl group in R1 of the cephem nucleus. They have good penetration through the outermost cell membrane and low affinity for type 1 β -lactamases, reducing their enzymatic degradation compared to other cephalosporins (Garau et al., 1997). They have a broad-spectrum activity against strains of Enterobacteriaceae resistant to ceftazidime, Gram-positive pathogens such as *S. aureus* (except methicillin and cefazolin-resistant strains), etc. (Devansh and Kumar, 2015). Cephalosporins are used to treat nosocomial and community infections, urinary with/without bacteremia, skin, soft tissues, the female reproductive system, the lower respiratory tract, in surgery, in febrile states of neutropenic patients, and critically ill patients (Devansh and Kumar, 2015). Among the cephalosporins of this generation is Cefepime/Cefepime (Thomson et al., 2019). Its affinity for PBP-2 places it as an adequate option against Gram-negative that are resistant to 3rd generation cephalosporins. Its spectrum includes Gram-negative and Gram-positive, but it has no action against enterococci or bacteroids. Generally, it is used to treat infections produced by *P. aeruginosa*, *S. aureus*, *S. pneumoniae*, etc. (Bhagwat et al., 2020; Moya et al., 2021).

Fifth generation cephalosporins include Ceftaroline, which was developed by modifying cefozopran. Ceftaroline is the only drug effective against multi-resistant *S. aureus*, including VRSA and VISA and it is the only beta-lactam antibiotic with activity against MRSA (Frampton, 2013).

Carbapenems

Carbapenems are broad-spectrum antibiotics, stable against extended spectrum and chromosomal β -lactamases. They are not active against carbapenemase-producing strains, ampicillin-resistant enterococci, methicillin-resistant staphylococci (MRSA, SCNRM), *Enterococcus faecium*, *C. difficile*, *Stenotrophomonas* and *Burkholderia*. They are used for serious nosocomial infections and against infections caused by multi-resistant Gram-negative bacteria or producers of broad-spectrum and extended-spectrum β -lactamases. Among these antibiotics is Imipenem, which was the first antibiotic belonging to this group. Imipenem inhibits the third and last stage of cell wall synthesis, has the widest spectrum of activity of all known antibiotics (Lob et al., 2017). It is prescribed for infections present in the valves and lining of the heart, respiratory tract (including pneumonia), urinary tract, abdominal (stomach), gynecological, blood, skin, bones and joints. Another antibiotic belonging to this group is meropenem, that acts in a similar way to imipenem. Resistance to meropenem arises from the decrease in the permeability of the outer membrane in Gram-negative (due to loss of porins), the reduction of affinity of the target PBPs, efflux pumps and β -lactamases (Niu et al., 2020).

Ertapenem is another member of the carbapenems, yet more effective than imipenem. Ertapenem is not sensitive to broad-spectrum β -lactamases and penicillases. It is generally used for the treatment of infections caused by bacteria resistant to other groups of antibiotics, as a solution to intra-abdominal infections, to treat acute gynecological infections, pneumonia infections, diabetic foot infections, and infections that affect the skin and tissues, etc. The most frequent resistance mechanism to this antibiotic is produced by the hyperproduction of plasmid β -lactamases such as OXA-1, TEM-1, TEM-2 or SHV-1 or IRT (Zhanel et al., 2005).

Monobactams are antibiotics that have a monocyclic nucleus and a β -lactam ring. They are bactericidal, and mainly used in infections of the lower respiratory tract, skin and soft tissues, intra-abdominal, and urinary and gynecological infections caused by *P. aeruginosa* and aerobic Gram-negative bacilli. Monobactams are synergistic with aminoglycosides and are recommended for patients with allergies to penicillin or cephalosporins. An example is Aztreonam, used to treat infections caused by Gram-negative anaerobic bacilli such as meningitis, bacteremias, skin and soft tissue infections, urinary, respiratory, and abdominal infections (Ramsey and MacGowan, 2016; Jorth et al., 2017; Chew et al., 2018). The main causes of resistance to Monobactams are efflux pumps. There are different β -lactams used in combination with inhibitors such as clavulanic acid, sulbactam and tazobactam. For instance, Amoxicillin/Clavulanic acid are used in therapeutic doses against acute and chronic infections of the upper and lower respiratory tract, in meningitis, in genitourinary, skin and soft tissue, gastrointestinal, and biliary infections, etc. (Jorth et al., 2017). Other effective combinations are Piperacillin/Tazobactam, recommended as a treatment for skin and soft tissue infections, gynecological and abdominal infections, and in neutropenic patients who present with fever due to infections of bacterial origin (Harris et al., 2018). Ceftazidime/Avibactam is used as a treatment in intra-abdominal and urinary tract (mainly pyelonephritis) infections, pneumonia (associated with mechanical ventilation), etc. (Zhanel et al., 2005). Ceftolozane/Tazobactam is used as a treatment for intra-abdominal infections, acute pyelonephritis, complicated urinary tract infections, and hospital-acquired lung infections (Puzniak et al., 2021).

Glycopeptides

Glycopeptides are one of the latest resources to combat infections by several Gram-positive bacteria. They are used to treat community acquired infections, and those acquired in a hospital environment. They are used to eradicate infections produced by *S. aureus*, including MRSA, resistant *Enterococcus* spp., and *Clostridioides difficile* (Jovetic et al., 2010; Butler et al., 2014). Members of the first generation are vancomycin and teicoplanin, isolated from *Amycolatopsis orientalis* and *Actinoplanes teichomyceticus* respectively; second generation members were the result of chemical derivatizations and, hence, semi-synthetic antibiotics, and include oritavancin, telavancin and dalbavancin (Marcone et al., 2018).

The core of these antibiotics consists in heptapeptides, which can be glycosylated tricyclic or tetracyclic. Both vancomycin and teicoplanin share chemical structures with high similarity. Vancomycin possesses aliphatic amino acids at position 1 and 3 at the N-terminal, whereas teicoplanin possess a lipophilic moiety linked to the vancosamine sugar (Sarkar and Haldar, 2019).

Glycopeptides inhibit the step of cell wall synthesis (Sarkar and Haldar, 2019). This is due to the binding to the D-alanyl-D-alanine (D-Ala-D-Ala) C-terminal together with the lipid II and the precursor of peptidoglycan (Marcone et al., 2018) preventing the incorporation of these components to the biosynthesis pathway (Blaskovich et al., 2018). This crosslinking is the result of the cooperative effect between five hydrogen bonds and disrupts transglycosylation and transpeptidation.

Resistance mechanisms against glycopeptides include changes in the configuration of the biosynthesis of the cell wall (Leclercq et al., 1988).

Changes that produce resistance, include the incorporation of D-lactate (D-Lac) or D-serine (D-Ser) to the peptidoglycan, as well as the activity of enzymes such as D-amino acids ligase and others able to degrade normal peptidoglycan precursors (Cattoir and Leclercq, 2013).

In target modification, D-Ala-D-Lac associated genes are *vanA* (phenotype inducible) and can be in plasmids or chromosomes. These genes are associated with high resistance to vancomycin and teicoplanin and are present in *Enterococcus* spp., and *S. aureus*; *vanB* (inducible). D-Ala-D-Lac associated genes confer resistance in variable levels to vancomycin and teicoplanin, and those genes are in plasmids and chromosomes, *vanD* (constitutive) confers moderate resistance to vancomycin and teicoplanin and it is located in the chromosome, present in *Enterococcus faecalis* and *E. faecium*, while *vanM* confers resistance to teicoplanin and vancomycin and it can be found in *E. faecium*, finally, *vanA* and *vanB* occasionally have been found in coryneform and streptococci.

Meanwhile, *vanC* genes are associated with D-Ala-D-Ser and are both constitutive and inducible and are found in *Enterococcus gallinarum*, and *Enterococcus casseliflavus*; *vanE*, also can be inducible or constitutive and is present in *E. faecalis*; *vanG* and *vanL*, both are inducible and present in *E. faecalis* and *vanN* is constitutive in *E. faecium*. All of them confer resistance to vancomycin (Cattoir and Leclercq, 2013; Butler et al., 2014).

Fosfomycin

In 1969, Hendlin and colleagues discovered fosfomycin, produced by *Streptomyces* spp. It is an analog of phosphoenolpyruvate, composed of an epoxide ring and a carbon-phosphorus bond. It has a low molecular weight (138 g/mol) and is commercially available in 2 oral formulations (trometamol and calcium), and intravenously (disodium) (Falagas et al., 2016).

It functions by interfering with the first cytoplasmic step in the formation of the cell wall. The inhibition is achieved by the covalent binding of fosfomycin with the amino acid Cys115, the active site of the enzyme UDP-N-acetylglucosamine enolpyruvyl transferase (MurA). The enzyme MurA is responsible for catalyzing the formation of UDP N-acetylmuramic acid (UDP-MurNAc), a precursor of peptidoglycan (Olesen et al., 2014; Falagas et al., 2016).

Fosfomycin's spectrum of action includes Gram-positive cocci and Gram-negative rods. *Enterococcus* spp. (*E. faecalis*, *E. faecium*) and *Staphylococcus* spp. (*S. aureus*, *S. epidermidis*) are susceptible (Vardakas et al., 2016).

Fosfomycin is also effective against extended-spectrum β -lactamase-producing and carbapenem-resistant bacteria (Bassetti et al., 2019). Uropathogens such as *E. coli*, *Klebsiella* spp., *Citrobacter* spp., *Proteus* spp., and *Enterobacter* spp., have susceptibilities ranging from 80% to 100% depending on the series (Vardakas et al., 2016; Bassetti et al., 2019; Wijma et al., 2019). *Morganella* spp. shows intrinsic resistance (Stock and Wiedemann, 1998).

In *P. aeruginosa*, CLSI and EUCAST have not established susceptibility cutoff points, however, recent research supports the use of this drug in isolates of *P. aeruginosa*, taking an epidemiological cutoff value lower than <128 $\mu\text{g/L}$ as susceptible (EUCAST). A recent analysis found a 62% susceptibility in an international collection of *P. aeruginosa* MDR strains (Mojica et al., 2020; Smith et al., 2020).

Fosfomycin enters the cell through two carrier-dependent systems: α -glycerophosphate (*Enterobacteriales*, *P. aeruginosa*, *Staphylococcus* spp., *Enterococcus* spp.) and hexose-phosphate (*Enterobacteriales*). Mutations in the *glp7* gene, which encodes α -glycerophosphate permease, result in resistance to this drug (Silver, 2017).

Intrinsic resistance occurs in *Mycobacterium* sp., *Chlamydia* sp. and *Vibrio* sp., given a change from cysteine to aspartate in the enzyme MurA, preventing the binding of fosfomycin (Olesen et al., 2014). Others, such as *Pseudomonas putida*, have alternate routes for the formation of peptidoglycan, avoiding the de novo formation of UDP-MurNAc. There are few reports of *E. coli* with a mutation in the enzyme MurA (Silver, 2017).

Different enzymes inactivate fosfomycin by degradation of the oxirane ring, which include Metalloenzymes such as: FoaA (*Klebsiella* spp., *Pseudomonas* spp.), FosB (*S. aureus*, *S. epidermidis*), FosX (*L. monocytogenes*, *Clostridium botulinum*, *Brucella melitensis*) and, recently, FosM (Bacillus species in human microbiota) (Fillgrove et al., 2007; Elliott et al., 2019; Khabthani et al., 2021). FoaA a glutathione-S-transferase present on the TN2921 transposon was originally described in a plasmid in *Serratia marcescens*. And two fosfomycin kinases: FomA and FomB, both present in *Streptomyces wedmorensis* also inactivate this drug (Silver, 2017). Fosfomycin is used in cystitis (Ten Doesschate et al., 2018), pyelonephritis (Kaye et al., 2019; Zhanel et al., 2020) and chronic prostatitis (Karaïskos et al., 2019). Given its wide distribution to tissues, it has also been used in osteomyelitis, meningitis and pneumonia (Falagas et al., 2016). Recent trials demonstrate synergy with meropenem for Metallo- β -lactamase-producing *P. aeruginosa* (Albiero et al., 2019); and Daptomycin for MRSA endocarditis (Pujol et al., 2021).

Lincosamides

Lincosamides are named after Lincoln, Nebraska, where they were first isolated from *Streptomyces lincolnensis*. It is considered a small pharmacological group; main members are lincosamide and clindamycin, the latter having greater biological activity and the most used in clinical practice. Lincosamides are derived from many species of *Streptomyces* and *Micromonospora halophytica*. The prototype of this group; Clindamycin has broad biological activity against anaerobic bacteria and some protozoa (Spížek and Řezanka, 2017).

Natural and semisynthetic lincosamides are A, B, C, D, S, K, K-celestines A, B, C, D, Desalination, Desalination D, and N-desmethyl celesticetin.

Lincosamides are formed by N-methyl-4-n-L-proline or propylhygric acid, linked by a peptide bond, with the sugar 6-amino-6,8-dideoxy-1-thio-D-galactopyranoside or methylthio-lincosamide. About 20 derivatives of different lincosamides are known. Lincosamides inhibit the first steps of protein production, promoting the termination of the chains that are produced in the ribosome. They bind the 50s ribosomal subunit and inhibit peptidyl transferase, halting protein synthesis. Clindamycin and other lincosamides are structural analogs of the 3' ends of 1-Pro-Met-tRNA and deacylated-tRNA interfering with the pre-translocation during peptide elongation (Spížek and Řezanka, 2017).

At therapeutic doses, lincosamide and clindamycin are considered bacteriostatic. The lincosamides spectrum of activity is wide, including against both aerobic and anaerobic species, and with good activity against staphylococcal and streptococcal species. In this instance, it has been shown that even in low concentrations, lincosamides have activity against the release of toxins. In anaerobic species, lincosamides have activity against fusobacterium, prevotella and bacteroides. Lincosamides also exhibit

activity against protozoa for the treatment of malaria, babesiosis, and toxoplasmosis. Clindamycin is the first line of treatment against *Capnocytophaga canimorsus* (Spížek and Řezanka, 2017).

Alternatively, lincosamides are useless for the treatment of infections by *Pseudomonas* spp., *Moraxella* spp., *Haemophilus* spp. *Neisseria* spp., due to intrinsic resistance. Of the main agents with biological activity, the cut-off values are for the case of *S. aureus* 0.016 µg/mL → 256 µg/mL, *S. pneumoniae* 0.002 µg/mL → 256 µg/mL, and *Streptococcus pyogenes* <0.015 µg/mL → 64 µg/mL.

The main mechanism of clindamycin resistance is methylation of the ribosome, which causes cross-resistance to macrolides, lincosamides, and streptogramins. Those methylation mechanisms are encoded by several *erm* (erythromycin ribosome methylase) genes, found in a wide variety of bacteria. The Erm protein, dimethylate, a single nascent 23s adenine, which is present in the 50s ribosomal subunit, decreases the affinity of clindamycin to its target. Since the binding sites of macrolides, lincosamides, and streptogramins B on 23S rRNA overlap, methylation causes cross-resistance towards the three antibiotic classes. To date, approximately 40 different *erm* genes have been described (Spížek and Řezanka, 2017).

Antibiotics that disrupt cell membranes

Polymyxins

Polymyxins are antibiotics that have recently gained interest for the treatment of infections caused by multi-resistant bacteria such as *P. aeruginosa* and *A. baumannii*. This group was described in 1947 by Benedict and Langlykke (1947) and by Ainsworth and coworkers, which described aerospurin derived from *Bacillus aerosporus* (Ainsworth et al., 1947).

In 1949, the Brownie classification system renamed polymyxin A to aerospurin and polymyxin B to polymyxin, later, polymyxin B, C and E (Brownlee, 1949). At the same time, in Japan, colistin was discovered and was later included in the group of polymyxins. Polymyxins were eventually abandoned, due to the potential nephrotoxic risk, and because other groups of antibiotics with the same activity were available. However, then multidrug resistant bacteria increased, and currently, polymyxins are now used again for their effectiveness. The two most used polymyxins are colistin and polymyxin B.

Polymyxins are cationic peptides consisting of a cyclic heptapeptide with a tripeptide side chain with a fatty acid tail at the N-terminus. The toxicity and activity are explained by this chain. Colistin and polymyxin B differ by one amino acid on the peptide ring; a phenylalanine for colistin and leucine for colistin. Colistin is administered as a drug known as colistimethate, unlike polymyxin B which is an active antibiotic (Li et al., 2006). Various mechanisms of action for polymyxins have been described. One of them lies in its activity against the outer membrane, due to an interaction of the residue of α , γ -diaminobutyric acid and the phosphate groups of the lipid A membrane. This interaction causes destabilization of lipid A, with a net effect of increasing the permeability of the bacterial membrane, causing leakage of the cytoplasmic material and the death of the bacteria. Another mechanism of action for polymyxins is binding endotoxin by interacting with lipid A, and promoting the inhibition of enzymes such as NADH-quinone oxidoreductase type II (Falagas and Kasiakou, 2005).

Alternatively, polymyxins have a narrow range of activity against most enterobacteria, including *E. coli*, *Salmonella* spp., *Shigella* spp., *Enterobacter* spp. and *Klebsiella* spp., as well as other Gram-negative bacteria such as *P. aeruginosa*, *A. baumannii* and *Stenotrophomonas maltophilia* (Deris et al., 2014). At present, The use of polymyxins focuses more on the treatment of infection by *P. aeruginosa* and *A. baumannii* (Tsuji et al., 2019). In the case of colistin, the target plasma concentration is 2 µg/mL, in bacteria with a MIC <1 µg/mL. Minimal post-antibiotic effects have been described at relevant clinical concentrations.

In 2019, in the United States, a MIC ≤2 mg/L is recommended as the susceptibility breakpoint for colistin and polymyxin B against *P. aeruginosa*, *A. baumannii* and Enterobacterales (Pogue et al., 2020). The EUCAST describes the polymyxin B cutoff for Enterobacterales (2 mg/L), *P. aeruginosa* (4 mg/L) and *Acinetobacter* spp. (2 mg/L).

Most of the pharmacokinetic data of polymyxins describe colistin. After administering colistin, a large proportion is eliminated via the kidneys, and between 20% and 25% of the drug is hydrolyzed in the active form. Therefore, colistin activity is influenced by renal function, and so regimens with colistin often require adjustment of dosing. In contrast to the prodrug active colistin is preferentially eliminated non-renally due to its extensive tubular reabsorption. Polymyxin B is also excreted by non-renal route, in which only 1% is isolated in urine, therefore it is not necessary to make a dose adjustment, despite having impaired renal function (Berg et al., 1998).

The basic molecular mechanisms by which polymyxin B increase transepithelial conductance in the urinary tract, are the same as for colistin, resulting in increased influx of cations, anions, and water, leading to inflammation and cell lysis. Currently, colistin toxicity is low, in part due to minimal chemical impurities in the drug, and also due to mechanisms related to the scope of administration, such as continuous monitoring in intensive care units. Potential negative side effects related to colistin are nephrotoxicity and neurotoxicity, the latter being dose-dependent and reversible. The most common neurotoxic effect is paresthesia. Nephrotoxicity is the most general adverse effect (Sorlí et al., 2013).

Although resistance against polymyxins is relatively rare, and more difficult to appear than to most antibiotics, resistance levels are rising. The main mechanism for resistance includes modification of the LPS structure, mainly by the reduction of their negative charge, that leads to a decrease in the affinity of the cationic peptides. The reduction of the negative charge is achieved by the addition of positive groups such, phosphoethanolamine, galactosamine and 4-amino-L-arabinose, most of them mediated by chromosomally encoded genes, although some plasmid born genes such as MCR phosphoethanolamine transferases are also involved. Another resistance mechanism is through losing the production of lipid A or LPS, through mutations in the genes encoding enzymes in charge of their biosynthesis, such as against polymyxins in *A. baumannii* (Olaitan et al., 2014).

Antibiotics that inhibit protein synthesis

Aminoglycosides are produced by actinobacteria of the genera *Streptomyces* ssp. and *Micromonospora* ssp. and are made up of the combination of two types of compounds: non-amino sugars (glucosides) or amino sugars (aminoglycosides) and non-amino cyclic alcohols (cyclitols) or amino acids (aminocyclotols). Aminoglycosides form three possible combinations, where the most important group is aminoglycoside plus aminocyclitol, which constitutes gentamicin, streptomycin and amikacin, the other groups are made up of glucoside plus aminocyclitol (spectinomycin) and aminoglycoside plus cyclitol (kasugamycin); they are water-soluble, stable and more active in alkaline pH.

Aminoglycosides have a high bactericidal activity, which is higher than that of β -lactams; they inhibit protein synthesis in an irreversible way, entering bacteria by passive diffusion through porines in the outer membrane, and they are later actively transported from the membrane to the cytoplasm. Within the cell, they bind to specific regions of the 30s subunit of the ribosome, inhibiting protein synthesis by three mechanisms: (1) interference with the initiation of the peptide formation complex; (2) erroneous reading of the mRNA, giving rise to a non-functional proteins; (3) disintegration of polysomes into non-functional monosomes. These three mechanisms occur simultaneously, causing an irreversible and lethal effect on the cell (Busse et al., 1992).

Aminoglycosides are used for the treatment of infections caused by aerobic Gram-negative bacilli. In addition, they are combined with β -lactams to achieve synergism in activity against some Gram-positives and against *Mycobacterium* spp. Anaerobes are resistant to aminoglycosides.

Streptomycin was used as the first antibiotic against infection caused by *Mycobacterium tuberculosis*. Currently, Streptomycin is part of the second line of treatment in combination with penicillin G, it is also used for the treatment of bacterial endocarditis, caused by *Streptococcus viridans*. Gentamicin is used in serious infections such as septicemia and pneumonia; its use in combination with a β -lactam is recommended for infections caused by microorganisms that are resistant to other drugs such as: *P. aeruginosa*, *S. marcescens*, *Enterobacter* sp. and *Klebsiella* sp.

Another aminoglycoside, amikacin, is a synthetic derivative of kanamycin. Amikacin is resistant to enzymes that inactivate other aminoglycosides. Additionally, it is less toxic than other aminoglycosides. It is used in infections caused by *Proteus*, *Pseudomonas*, *Enterobacter* and *Serratia*, which become resistant to gentamicin.

To date, three resistance mechanisms against aminoglycosides are described: (1) inactivation of compounds by enzymes modifying aminoglycoside (EMA) that catalyze covalent modifications in the amino and hydroxyl groups, causing weak binding to their target site; (2) a decrease in the impermeability of the outer membrane and therefore a reduction in the intracellular concentration; (3) a deletion or alteration of their binding sites in the 30s subunit, as a result of mutations (Paul et al., 2013).

Macrolides

Macrolides are one of the most commonly used families of antibiotics prescribed to treat infections caused by Gram-positive bacteria such as *S. aureus*, *S. pneumoniae* and *S. pyogenes* (Gaynor and Mankin, 2005). Macrolides are bacteriostatic and inhibit protein synthesis. Although their exact mechanism of action varies depending on the specific macrolide, their primary action is the dissociation of peptidyltransfer RNA from the ribosomes during translocation. Macrolides bind to the 50S ribosome subunit of bacteria inhibiting transpeptidation and translocation of nascent peptides (Rollins et al., 2014).

Macrolides have at least 12-membered glycosylated macrolactone rings (Zin et al., 2020), and they are divided into different categories based on structural features. Erythromycin and clarithromycin are 14-membered lactone rings. Azithromycin is a part of the azalide subclass and contains a 15-membered ring (Fohner et al., 2017).

Macrolides are effective against Staphylococcus, Streptococcus and Diplococcus and among Gram-negative cocci, *Neisseria gonorrhoea*, *H. influenzae*, *Bordetella pertussis* and *Neisseria meningitis*. Furthermore, they are also extremely active against various Mycoplasmas (Dinos, 2017).

The five macrolide antibiotics available have a similar range of activities; however, clarithromycin and azithromycin are more active than erythromycin against several Gram-negative bacteria as well as *Mycoplasma pneumoniae*, *H. pylori*, and atypical mycobacteria. Fidaxomicin is not absorbed orally and is used to treat *Clostridium difficile* associated diarrhea (Bethesda, 2017).

Macrolides selectively inhibit the translation of a subset of cellular proteins, in that their action crucially depends on the nascent protein sequence and on the antibiotic structure to block protein elongation (Vázquez-Laslop and Mankin, 2018). During elongation, peptidyl transferase catalyzes the addition of a new amino acid to the growing peptide chain. The growing peptide chain is then translocated from the A site to the P site. It has been suggested that 16-membered macrolides inhibit the peptidyl transfer reactions, and that the 14-membered ones block the peptidyltransfer RNA (tRNA) translocation (Zhanel et al., 2001; Tacconelli et al., 2018).

Erythromycin has an antimicrobial spectrum similar to that of penicillin, and so was historically widely used in patients allergic to penicillin. Erythromycin has bacteriostatic and bactericidal activity, depending on the type of microorganism and the antibiotic concentration. It is most effective against *S. aureus*, streptococcal group A, enterococci, and pneumococci. It inhibits *Neisseria* and some strains of *H. influenzae*, *Pasteurella multocida*, *Brucella*, *Rickettsiae*, and *Treponema*. It is also effective against *Mycoplasma pneumoniae*, *Chlamydiae*, *Legionellae pneumophila*, and some other atypical mycobacteria (Jelić and Antolović, 2016). It is used for various respiratory infections, including community-acquired pneumonia and Legionnaires disease, as a prophylaxis of neonatal conjunctivitis, etc. It is also used for treating skin infections, syphilis, and pelvic inflammatory disease.

Clarithromycin and azithromycin are given orally for the treatment of respiratory infections and these drugs distribute to a variety of tissues, particularly to the lungs (Togami et al., 2011). Clarithromycin and azithromycin are also used for treating sexually transmitted diseases and *H. pylori* infections (Zuckerman et al., 2011).

Resistance to macrolide antibiotics is mediated by several mechanisms including: (i) decreasing their intracellular concentration, (ii) alterations of the target, (iii) protection of the target, and (iv) chemically inactivation of the antibiotics (Golkar et al., 2018).

Tetracyclines

Tetracyclines are broad-spectrum antibiotics active against Gram-positive and Gram-negative bacteria, such as spirochetes, and obligate (or obliterate?) intracellular bacteria (Grossman, 2016). The newest tetracyclines include eravacycline, omadacycline and eravacycline. The traditional tetracyclines are tetracycline, chlortetracycline, oxytetracycline and demeclocycline and semi-synthetic members are minocycline, doxycycline, lymecycline, rolitetracycline and lymecycline. Meanwhile, tigecycline, one of the most used, belongs to the subclass glycacycline (Sapadin and Fleischmajer, 2006; Nelson and Levy, 2011).

The core of Tetracyclines is made by four linear fused tetracyclic rings, which have a variety of functional groups (Chopra and Roberts, 2001). Since the first was discovered in 1948, it has been used in humans ever since, and remains one of the most prescribed antibiotics in the world. In general, tetracyclines are well-tolerated and available orally, intravenously, topically, and intramuscularly (Chopra and Roberts, 2001). Tetracyclines have good distribution in overall tissue, the ascitic area, the synovial and pleural fluids, and in lungs; however, they have poor perfusion to the cerebral spinal space.

In tetracyclines, the mechanism of action is binding to the bacterial ribosome, and thus inhibiting protein synthesis. To achieve this, tetracyclines must cross the Gram-negative membranes through porins such as OmpF and OmpC (Chopra et al., 1992; Schnappinger and Hillen, 1996). The ribosomal 30S subunit has a high-affinity binding site to tetracyclines, and both the 30S and 50S subunits have several binding sites with low-affinity, then an allosterical interaction with the amino acyl-tRNA at the acceptor site (A-site) interrupts protein synthesis (Griffin et al., 2010).

Resistance mechanisms against tetracyclines are either mediated by efflux pumps (McMurry et al., 1980), mainly from the Tet family protein, part of the major facilitator superfamily (Pasqua et al., 2019), or by the protection of ribosomes mediated also by proteins of the Tet family such as TetM and TetO (Taylor and Chau, 1996).

Oxazolidinones

The oxazolidinone group includes Tedizolid and Linezolid, FDA approved drugs. In 1987, the oxazolidinone structure was synthesized: 5-(halomethyl)-3-aryl-2-oxazolidinones, which served as the basis for the development of Linezolid, approved for clinical use in 2000 (Slee et al., 1987).

Both Tedizolid and Linezolid share multiple characteristics in their chemical structure. Tedizolid contains a hydroxymethyl group in ring A and a pyridine ring (ring C) and tetrazole (ring D) are added. In Linezolid, acetamide in ring A increases the antimicrobial activity of the drug. One of the main differences is their dosages; Tedizolid is administered once a day, while Linezolid is twice a day (Kisgen et al., 2014).

Oxazolidinones are inhibitors of protein synthesis by binding to the V domain of 23S ribosomal RNA in the 50S subunit, blocking the formation of the 70S unit and preventing ribosomal transcription.

Oxazolidinones show very good activity against Gram-positive cocci such as *S. aureus* (including MRSA), Ceftriaxone-resistant *Streptococcus pneumoniae*, *Streptococcus* spp., Vancomycin-resistant *E. faecium* and *Nocardia* spp. Oxazolidinones have moderate to good activity against *Mycobacterium* spp., mainly *M. tuberculosis*, where linezolid has gained a niche within second-line drugs for MDR strains; and some Gram-positive anaerobes such as *Bacillus* spp. and *Clostridium* spp. However, due to efflux pumps, the activity of oxazolidinones against Gram-negative bacteria is very poor. Tedizolid and Linezolid have the same spectrum of action, but Tedizolid has lower MICs (Bozdogan and Appelbaum, 2004; Pfaller et al., 2019; Ruiz et al., 2019).

In general, resistance to oxazolidinones is infrequent, however, induced resistance has been observed in *Enterococcus* spp. and *Staphylococcus* spp., where constant exposure increases MIC 32 times after 30 generations. On the other hand, there are 23S ribosomal RNA mutations that confer low-grade resistance described in *Enterococcus* spp. and *Staphylococcus* spp. High-grade resistance is transferred by plasmids or transposons that carry the CFR gene; This gene encodes a methyltransferase that methylates RNA 23S (A2503); however, the molecular structure of tedizolid allows it to retain activity against strains that present the CFR gene. There are other mutations in the gene encoding the ribosomal binding site such as L3 and L4, they have been identified in *Staphylococcus* spp., *S. pneumoniae* and *Clostridium perfringens*. The genes *optrA* and *poxA* have recently been found, which encode a cassette-bound ATP-like transporter protein that confers resistance to oxazolidinones (linezolid and tedizolid) and phenicols through a ribosome protection mechanism (Liu et al., 2020).

Current FDA indications for linezolid are primarily skin and soft tissue infections (Stevens et al., 2005), vertebral osteomyelitis (Berbari et al., 2015), MRSA pneumonia (Metlay et al., 2019), and MDR tuberculosis (TB) (Conradie et al., 2020). Currently, tedizolid is approved by the FDA only for the treatment of skin and soft tissue infections (Bouza et al., 2018).

Streptogramins

Streptogramins are naturally produced by *Streptomyces* and are classified in two groups A and B. They are bacteriostatic when used alone, but together they can become bactericidal. Group A streptogramins bind the bacterial ribosome at the P site, preventing protein elongation; they also promote a conformational change in the 50S subunit that enhances the activity of group B streptogramins, which also interfere with protein elongation and cause the release of incomplete peptides (Mukhtar and Wright, 2005). The most commonly prescribed combination is quinupristin/dalfopristin (both derived from *pristinamycin*); they are combined in a proportion of 70%/30% and administered intravenously to treat *staphylococci* and by *vancomycin*-resistant *E. faecium* infections. Resistance against these antibiotics is mediated by multiple mechanisms, including: efflux pumps, enzymatic modification, and mutations changing the target site (Hershberger et al., 2004).

Chloramphenicol

In 1947, Chloramphenicol was isolated from *Streptomyces venezuelae* and later from other *Streptomyces* species and currently is synthesized. Chloramphenicol has broad spectrum activity; however, since it is linked to some negative side effects such as bone marrow aplasia and grey baby syndrome, its current use is mainly restricted for treating eye infections such as conjunctivitis and blepharitis. It is bacteriostatic, and bactericidal against some bacteria such as *S. pneumoniae*, *N. meningitidis* and *H. influenzae*, at high concentrations. Chloramphenicol disrupts protein synthesis, binding the 50S subunit of the bacterial ribosome inhibiting transpeptidation. Resistance against this drug arises mainly due to the presence of the inactivating the enzyme chloramphenicol acetyltransferase, found commonly on plasmids. In addition, cross resistance to linezolid via *cfr* genes is also observed in some strains of *S. aureus*, and the reduction of the permeability and mutations in the 50S ribosome subunit can also lead to resistance (Eliakim-Raz et al., 2014).

Antibiotics disrupting nucleic acid synthesis

Quinolones

Quinolones are synthetic antibiotics with a bicyclic core structure derived from 4-quinolone. They were discovered in the 1960s, as nalidixic acid the first to be discovered (Pham et al., 2019). Later on, fluorination of these compounds lead to the obtention (→ what word do you want to say here? invention?) of fluoroquinolones, enhancing their activity spectrum (Pham et al., 2019). They are bacteriostatic and their mechanism of action consists in binding and inhibiting topoisomerases (gyrase, type II and type IV), hence promoting supercoiling, DNA damage and halting DNA synthesis (Aldred et al., 2014). Quinolones are used mainly for the treatment of genitourinary track infections and for nosocomial infections associated with urinary catheters, as well as for complicated prostatitis and pyelonephritis (Liu and Mulholland, 2005). They are also prescribed occasionally for the treatment of respiratory and gastrointestinal infections, and soft tissue, skin and tuberculosis infections (Aldred et al., 2014).

Currently there are four quinolone generations: nalidixic acid, ciprofloxacin, levofloxacin and moxifloxacin. Their activity spectrum originally was mainly against Gram-negative bacteria, except for *Pseudomonas*, but more recent generations include some activity against Gram-positive bacteria including *S. aureus*, and atypical bacteria such as *M. pneumoniae* and *Chlamydia pneumoniae* (Pham et al., 2019).

Ciprofloxacin is prescribed orally, intravenously, or as eye and ear drops. It is active against *Pseudomonas*, and prescribed for urinary, intra-abdominal, joint, and skin infections, typhoid fever, prostatitis, genital infections and infectious diarrhea and for prophylaxis in prolonged cancer treatments (Sharma et al., 2010).

Levofloxacin has broad activity against Gram-negative and Gram-positive bacteria, atypical respiratory pathogens and *S. pneumoniae*, hence is used for the treatment of the respiratory tract, the genitourinary tract and skin infections (Croom and Goa, 2003).

Moxifloxacin is a fourth-generation fluoroquinolone used for the treatment of sinusitis, eye infections, endocarditis, pneumonia and tuberculosis (TB). For TB, it is prescribed when there is intolerance against one of the first-line drugs, or when mycobacteria are resistant against isoniazid. Moxifloxacin is also included in several novel combinatory treatments for TB showing promising results (Naidoo et al., 2017).

Fluoroquinolone resistance is mediated by several, not exclusive, mechanisms: (1) mutations in the targets topoisomerases and gyrase that decrease the affinity for the drugs, (2) downregulation of porin expression, decreasing its uptake, (3) efflux pumps, either encoded in the chromosome or in transmissible plasmids, (4) protection of the targets by specific proteins (Qnr, McbG and MfpA) that bind to them and decrease the drug binding, (5) enzymatic inactivation of the drugs, specifically acetylation mediated by mutated aminoglycoside acetyltransferases such as *aac(6′)-Ib-cr* (Aldred et al., 2014).

Rifampicin

Isolated in 1968, rifampicin belongs to the rifamycins, produced by the strain *Ammycolatopsis mediterranei*. The main use of rifampicin is for the treatment of several mycobacterias, mainly *M. tuberculosis*; however, it can also be used in infections associated with prosthetic infections caused by *S. aureus*, and also to treat *Clostridioides difficile* and some Gram-negative infections such as

N. meningitidis, *N. gonorrhoeae* and *H. influenzae* (Rothstein, 2016). Rifampicin has been promoted as bactericidal, however, results from the ARREST study did not show better results with the use of rifampicin against *S. aureus* in bloodstream infections in comparison with a placebo group ([https://doi.org/10.1016/S0140-6736\(17\)32456-X](https://doi.org/10.1016/S0140-6736(17)32456-X)). However, in vitro, there is evidence about the utility of rifampicin, such as an anti-biofilm molecule.

Rifampicin's antimicrobial action is carried out due RNA synthesis inhibition, blocking sterically the activity of DNA-dependent RNA polymerase, therefore decreasing its affinity with short RNA transcripts and stopping RNA elongation at the 5' end. This molecule has no activity on mammalian RNA polymerases (McClure and Cech, 1978; Schulz and Zillig, 1981; Campbell et al., 2001).

Resistance to rifampicin is conferred mainly to the mutation of the *rpoB* gene, particularly in *M. tuberculosis*, rifampicin being highly used as part of the first line of treatment. Once mutations appear, rifampicin's ability to bind to RNA polymerase decreases drastically. Resistance to rifampicin also has been observed in those microorganisms on the *arr* gene; these genes encode enzymes (that ribosylate rifampicin inactivating it.) (this does not make sense) The *arr* genes have been found in *Mycobacterium smegmatis*. In addition, a similar *arr2* gene is present in plasmids in clinical strains of *Enterobacterales*, such as *Klebsiella*.

Antibiotics that disrupt bacterial metabolism

Sulfonamides

Sulfonamides are analogs of para aminobenzoic acid (PABA). They are poorly soluble in water, but their sodium salts are much more soluble. The structural features responsible for their antibacterial activity include the presence of a sulfur linked to the benzene ring, and the presence of the para-NH₂ group, that can only be replaced by moieties that can be transformed in vivo, to a free amino group (Smith and Powell, 2000).

Sulfonamides are competitive inhibitors of the enzyme dihydropteroate synthase, which is responsible for incorporating PABA, into dihydropteroic acid, the precursor of folic acid. Sensitive bacteria are those that synthesize their own folic acid. Hence bacteria (and all mammalian cells) that can use preformed folate, are not affected by these drugs.

Sulfonamides are bacteriostatic and inhibit both Gram-positive bacteria, such as *Staphylococcus* sp., as well as Gram-negative enteric bacteria such as *Escherichia coli*, *Klebsiella pneumoniae*, *Salmonella*, *Shigella*, and *Enterobacter* sp., *Nocardia* sp., *Chlamydia trachomatis*, etc. Sulfonamides do not inhibit rickettsiae, but rather stimulate their growth. Their activity against anaerobes is poor, and *P. aeruginosa* is inherently tolerant to them (Smith and Powell, 2000).

Sulfonamides are effective for treating *P. jirovecii* pneumonia, urinary tract infections, prostatitis, and infections caused by some strains of *Shigella*, *Salmonella*, and atypical mycobacteria. Sulfonamides are active against MRSA and methicillin-sensitive *S. aureus*, and against respiratory tract pathogens such as *Haemophilus* sp., *M. catarrhalis*, and *K. pneumoniae*, but not against *M. pneumoniae*.

Sulfonamides are also an effective alternative against infections caused by species such as *Enterobacter* and *Serratia*, shigellosis or typhoid fever, as well as for serious *Listeria* infections in patients allergic to ampicillin (Smith and Powell, 2000).

Bacterial resistance to sulfonamides can be caused by mutations or transfer of resistance by plasmids; sulfonamides generally do not generate cross-resistance. Resistance to sulfonamides is mediated by: (1) a lower affinity of the drugs towards dihydropteroate synthase; (2) decreased bacterial permeability; (3) active drug release; (4) the presence of alternative metabolic pathways for the biosynthesis of folic acid; or (5) increased production of an essential metabolite or drug antagonist, such as PABA (Sköld, 2000). Plasmid-mediated resistance is due to plasmid-encoded resistant dihydropteroate synthase (Sköld, 2000).

Novel antibiotics

In recent decades, research into new antibiotics has increased, although not to the levels found in the decades from 1940 to 1960. The present priority is to combat multidrug resistant bacteria (MDR), extensively drug resistant (XDR) and Gram ESCAPE pathogens that are a threat to humanity (Hutchings et al., 2019; López-Jácome et al., 2019).

Most of the antibiotics currently approved worldwide continue to be obtained from natural products of bacteria mainly of the genus (Actinomycetes) and fungi. In recent years, the use of bioinformatic tools, such as next generation sequencing, genome mining and CRISPR/Cas9-mediated genome editing and network biology methods, could assist researchers to discover better antibiotics, antibiotic combinations, and drug repurposing in the coming years (Kohanski et al., 2010; Hutchings et al., 2019).

Published in December 2020, the latest global review on antibiotics in development notes that there are 43 new antibiotics that are in different stages of development; 15 are in phase 3, 13 in phase 2, and 13 in phase 1, and two antibiotics have the category of application of new drugs submitted to the Food Drug and Administration (FDA) in the United States and the National Medical Products Administration of China.

In addition to the usual targets for antibiotics, new targets and new drugs have also been reported and are currently being tested. For example, Gepotidacin (GSK2140944) (phase 3), an organic synthetic compound that has shown activity against Gram-positive and Gram-negative bacteria, inhibits bacterial DNA gyrase and topoisomerase IV (Flamm et al., 2015; Hsu et al., 2019). Another example is Afabacin (Debio 1450) (phase 2), also a synthetic organic compound that has shown activity against Gram-positive bacteria, mainly *S. aureus* (Flamm et al., 2015). Its bacterial targets are focused on inhibiting FabI, the NADH-dependent enoyl reductase from the type II bacterial fatty acid biosynthesis pathway (FAS-II) (Flamm et al., 2015; Peyrusson et al., 2020).

Approving a new antibiotic to be used by the entire population is complicated. However, teixobactin is one of the few recently discovered antibiotics that has a wide application landscape. Teixobactin is a depsipeptide that contains D-amino-acids and L-allo-enduracididine residues (Ling et al., 2015; Shukla et al., 2020). The compound is produced by the species *Eleftheria terrae*,

a β -Proteobacteria Gram-negative related to the genus *Aquabacterium* (Ling et al., 2015; Shukla et al., 2020). Teixobactin has shown to be an important bactericide against MDR, such as *S. aureus*, *M. tuberculosis*, and MRSA (Ling et al., 2015; Lewis et al., 2018). Among the particularities that this antibiotic presents is its mechanism of action: the molecule binds to two precursor polymers of the cell wall lipid II (peptido-glycan) and lipid III (teichoic acid), producing a rapid lysis of the cell (Ling et al., 2015). Furthermore, it has recently been suggested that teixobactin interferes with cell wall biosynthesis (Shukla et al., 2020). Its mechanism of action, different from other antibiotics, makes it unlikely that resistance against teixobactin will develop (Ling et al., 2015). Teixobactin is currently in the last stage of preclinical development.

Finally, another important antibiotic that is new is sideromycins, that is, antibiotic-siderophore conjugates, or organic chelating agents, with high affinity for iron (Negash et al., 2019).

Iron is an essential element in many cellular processes, although it is scarce in pathogen-host interactions, so bacteria compete for it with the host. In November 2019, the first sideromycin, Cefiderocol (S-649266), a conjugated cephalosporin to the iron-chelating catechol group, was approved by the FDA (Aoki et al., 2018). The main mechanism of action of Cefiderocol acts as a Trojan horse, since once the catechol group of Cefiderocol forms an iron complex with the Fe^{3+} ion, it can penetrate (active transport pathway) the outer membrane of Gram-negative bacteria, increasing the concentration of the antibiotic in the periplasmic space (Ito et al., 2016). Cefiderocol is highly effective against MDR bacteria such as *P. aeruginosa*, *Burkholderia cepacia*, *A. baumannii*, and Enterobacteriaceae (Zhanel et al., 2019). Another promising compound is Ga^{3+} (gallium nitrate) which is a non-REDOX active Fe^{3+} analog. Gallium Nitrate has been previously used for treating hypercalcemia of malignancy, and it is also effective against MDR *P. aeruginosa* and *A. baumannii* *in vitro* and in animal models (Minandri et al., 2014). Gallium Nitrate also apparently has low levels of resistance (Kaneko et al., 2007; Goss et al., 2018; Tovar-García et al., 2020) and has shown effectivity in clinical trials to improve the lung function of patients with cystic fibrosis infected with *P. aeruginosa* (Goss et al., 2018).

A summary of the antibacterial discussed here is found in Table 1.

Table 1 Antibiotics included in the chapter.

Antibiotic target	Class	Representative example	Activity spectrum	Resistance mechanisms
Cell wall	β -lactams/penicillins	Amoxicillin	<i>Streptococcus</i> sp. <i>Enterococcus</i> sp. <i>Neisseria</i> sp. <i>Haemophilus influenzae</i> <i>Fusobacterium</i> sp. <i>Peptostreptococcus</i> sp. <i>Actinomyces</i> sp.	Penicillinases alterations of PBP2A
	β -lactams/Cephalosporins	Ceftriaxone	<i>Streptococcus</i> sp. <i>Staphylococcus</i> sp. <i>Neisseria gonorrhoeae</i> . <i>Leptospira interrogans</i> <i>Treponema pallidum</i> Enterobacteriaceae	Extended spectrum B-lactamase AmpC beta-lactamase alterations of PBP2A
	β -lactams/Carbapenems	Meropenem	<i>P. aeruginosa</i> <i>Acinetobacter baumannii</i> Enterobacteriaceae <i>Streptococcus</i> sp. <i>Staphylococcus</i> sp. <i>Nocardia</i> sp. <i>Rhodococcus equi</i> Anaerobic gram positive cocci and Gram-negative rods	Carbapenemases Hyperproduction of beta-lactamases Efflux OprM system OprD system alterations of PBP2A
	Glycopeptides	Vancomycin	<i>Staphylococcus</i> sp. <i>Streptococcus</i> sp. <i>Enterococcus</i> sp. <i>Listeria monocytogenes</i> <i>Bacillus</i> sp. <i>Clostridioides difficile</i> Enterobacteriaceae	Target modification in cell wall, genes: <i>vanA</i> , <i>vanB</i> , <i>vanC</i> , <i>vanD</i>
	Fosfomycin	Fosfomycin	<i>Enterococcus</i> sp. <i>Staphylococcus</i> sp. <i>P. aeruginosa</i>	Target modification: MurA. Metalloenzymes: FosA, FosB, FosX, FosM
	Lincosamides	Clyndamicin	<i>P. aeruginosa</i> Bacteroides sp. <i>Fusobacterium</i> <i>Prevotella</i> <i>Staphylococcus</i> sp. <i>Streptococcus</i> sp. <i>Capnocytophaga canimorsus</i>	Fosfomycin kinases: FomA, FomB ribosomal target methylation: erm gene

Table 1 (Continued)

<i>Antibiotic target</i>	<i>Class</i>	<i>Representative example</i>	<i>Activity spectrum</i>	<i>Resistance mechanisms</i>
Cell membranes				
	Polymyxins	Colistin	<i>P. aeruginosa</i> <i>A. baumannii</i> <i>Enterobacteriaceae</i>	Modification of the LPS structure, MCR1 gene
Protein synthesis inhibition				
	Aminoglycosides	Amikacin	<i>P. aeruginosa</i> <i>A. baumannii</i> <i>Enterobacteriaceae</i> <i>Nocardia</i> sp. <i>Rhodococcus equi</i> <i>Mycobacterium</i> sp. <i>Streptococcus</i> sp. <i>Enterococcus</i> sp.	Enzymes modifying aminoglycoside (EMA) Target modification Decrease in the permeability of the outer membrane
	Macrolides	Azithromycin	<i>Staphylococcus</i> sp. <i>Streptococcus</i> sp. <i>Mycoplasmas</i> sp. <i>Legionella</i> sp. <i>Helicobacter pylori</i> <i>C. jejuni</i> <i>Chlamydia</i> sp.	Target modification: erm gene Chemically inactivation Decreasing their intracellular concentration
	Tetracyclines	Doxycycline	<i>Enterobacteriaceae</i> <i>Streptococcus</i> sp. <i>Staphylococcus</i> sp. <i>Mycoplasmas</i> sp. <i>Legionella</i> sp. <i>Chlamydia</i> sp. <i>Rickettsiae</i> sp. <i>Vibrios</i> sp.	efflux pumps: Tet protection of ribosome: TetM and TetO
	Oxazolidinones	Linezolid	<i>Staphylococcus</i> sp. <i>Streptococcus</i> sp. <i>Enterococcus</i> sp. <i>L. monocytogenes</i> <i>Bacillus</i> sp.	Target modification Methyltransferase: CFR gene protection of ribosome: L3, L4, optrA, poxtA genes
	Streptogramins	Quinupristin/dalfopristin	<i>Mycobacterium</i> sp. <i>Staphylococcus</i> sp. <i>Enterococcus</i> sp.	Efflux pumps Enzymatic modification Target modification
	Chloramphenicol	Chloramphenicol	<i>Enterobacteriaceae</i> <i>Streptococcus</i> sp. <i>Staphylococcus</i> sp. <i>Enterococcus</i> sp. <i>Actinomyces</i> sp. <i>Vibrios</i> sp. <i>Rickettsiae</i> sp.	chloramphenicol acetyltransferase <i>cfr</i> gene
Disrupt nucleic acid synthesis				
	Quinolones	Levofloxacin	<i>P. aeruginosa</i> <i>Enterobacteriaceae</i> <i>Streptococcus</i> sp. <i>Staphylococcus</i> sp. <i>Mycoplasmas</i> sp. <i>Legionella</i> sp. <i>Chlamydia</i> sp. <i>Rickettsiae</i> sp. <i>Vibrios</i> sp. <i>Mycobacterium</i> sp. <i>Kingella</i> sp. <i>Yersinia</i> sp.	Target modification. GryA, GryB protection of the targets: Qnr
	Rifamycins	Rifampicin	<i>Mycobacterium</i> sp. <i>Staphylococcus</i> sp. <i>Neisseria</i> sp. <i>H. influenzae</i>	Target modification: <i>rpoB</i> gene ribosylate rifampicin: <i>arr</i> gene
Bacterial metabolism disruption				
	Sulfonamides	Trimethoprim/sulfamethoxazole	<i>Enterobacteriaceae</i> <i>Streptococcus</i> sp. <i>Staphylococcus</i> sp. <i>Nocardia</i> sp. <i>Moraxella</i> sp.	Lower affinity of dihydropteroate synthase. Decreased bacterial permeability Alternative metabolic pathway

Acknowledgments

Glossary

Acoziborole Synonyms: SCYX-7158; AN5568, 4-fluoro-*N*-(1-hydroxy-3,3-dimethyl-2,1-benzoxaborol-6-yl)-2-(trifluoromethyl benzamide, hydrogen bond donor and acceptor, is an orally active anti-protozoan, efficacious and safe for treatment of African trypanosomiasis via targeting mRNA maturation factors.

Benznidazole Is a nitroimidazole anti-Chagas disease agent, apparently reduced by *Trypanosoma cruzi* nitroreductases to various electrophilic metabolites, able to bind to and damage the parasite proteins, lipids, DNA, and RNA.

Eflornithine Difluoromethylornithine, a repurposed anti-tumor agent, enters trypanosomes via the amino-acid transporter AAT6, and irreversibly inhibits ornithine decarboxylase which catalyzes the biosynthesis of polyamines, critically important for trypanosomes cell growth, differentiation and replication. It is important for oral or intravenous treatment of West African trypanosomiasis.

Fexinidazole Is an all oral drug active against human African trypanosomiasis and visceral leishmaniasis. It is a nitroheterocyclic compound, belonging to the class of nitroimidazoles, readily reduced by parasitic protozoans nitroreductase to fexinidazole sulfoxide and fexinidazole sulfone, cytotoxic species that damage the parasite DNA, RNA, and proteins.

Folinic acid 5-Formyltetrahydrofolate, known as leucovorin, is readily converted to other reduced folic acid derivatives. It displays vitamin activity equivalent to that of folic acid and, hence, is used to treat folate deficiency, and decrease the toxicity of chemotherapeutic drugs. It is often prescribed in the treatment of toxoplasmosis retinitis, in combination with the folic acid antagonists pyrimethamine and sulfadiazine.

Kinetoplast A network of circular DNA (called kDNA) inside a large mitochondrion lying close to the nucleus, near to the base of the flagella, in some flagellate protozoa, the kinetoplastids. The thousands of circular, interlocking DNA chains/rings of kDNA represent approximately 15% of the total protozoal cell. Despite location near the base of the flagella, kinetoplasts are not involved in the protozoan motility. African trypanosomes (African sleeping sickness), *Trypanosoma cruzi* (Chagas' disease), and *Leishmania* species (leishmaniasis) are kinetoplastids.

Melarsoprol Arsobal, C₁₂H₁₅AsN₆OS₂, an aromatic arsenical belongs to the class of aniline and substituted anilines, containing an aminobenzene moiety. Melarsoprol enters trypanosomes via aquaglyceroporin (AQP2) transporter, with resistant strains showing mutations in this parasite solute and drug transporter. Melarsoprol inhibits a reductase enzyme responsible for reduction of trypanothione, a low molecular weight peptide containing spermidine and glutathione skeletons in a cyclic structure (*N*¹, *N*⁸-bis-(glutathionyl)-spermidine). In kinetoplastids, trypanothione replaces intracellular glutathione and glutathione reductase, the principal mechanism of the thiol-redox system. Reduced trypanothione plays an important role in maintaining intracellular thiol redox potentials, in protection of the parasite against oxidative and chemical stress, and in regulation of spermidine contents in the cells.

Nifurtimox A nitrofurant antiprotozoal drug is reduced by cytosol enzymes or flavin-containing microsomal enzymes to highly reactive nitro anion free radicals, which alkylate nucleic acids and proteins, resulting in the disruption of their structure and function. Auto-oxidation of the nitro anion free radical generates superoxide anion (O₂⁻) selectively toxic to the parasite.

Ookinete Malaria gametocytes ingested with a blood meal transform within the mosquito midgut into mature female and male gametes. The product of fertilization, a round-shaped zygote, transforms within a day into a crescent-shaped motile ookinete, which then traverses the midgut epithelium to the basal side, where it matures in about 2 weeks into oocyst. Oocytes break open and release thousands of sporozoites that migrate to the insect's salivary glands, ready for infection transmission.

Pyrimethamine Is an aminopyrimidine substituted at position 5 by a p-chlorophenyl group and at position 6 by an ethyl group. It is a folic acid antagonist, as it readily inhibits parasite dihydrofolate reductase, a key enzyme in the redox cycle for production of tetrahydrofolate, a cofactor that is required for the synthesis of DNA and proteins.

Nomenclature

ALB	Albendazole
DALYs	Disability-adjusted life years
DEC	Diethylcarbamazine citrate
HAT	Human African trypanosomiasis
Iv	Ivermectin
LF	Lymphatic filariasis
VSG	Variant surface glycoproteins

Parasitic protozoans (unicellular, prokaryotes)

African trypanosomiasis

Life cycle. Trypanosomiasis, a potentially fatal disease if not properly treated, is caused by unicellular, (25–40 $\mu\text{m} \times 1.5\text{--}3.5 \mu\text{m}$), flagellated protozoan parasites of the genus *Trypanosoma*, which require man and domestic animals as primary host, and blood-sucking insect as the intermediate host. The blood-sucking insect is responsible for the transmission of the parasites from one host to another during a blood meal. African trypanosomiasis is transmitted by several species of both male and female tsetse flies belonging to the genus *Glossina* (Despommier et al., 2005). It is caused in humans by *Trypanosoma brucei rhodesiense* (Eastern and Southern Africa) and *T. brucei gambiense* (Western and Central Africa), while the animal form of the disease is mostly caused by *T. congolense*, *T. vivax*, and *T. brucei brucei*. More than 65 million people living in 36 countries in sub-Saharan Africa are at risk of contracting the disease. At least 300,000–500,000 people are presently infected and only 10% of the new cases are diagnosed and treated. The disease is fatal because the parasite, despite being predominantly blood-borne, dwells in lymph and tissues, and readily affects the central nervous system (Baral, 2010; Brun et al., 2010; Onyilagha and Uzonna, 2019). Infection of livestock causes dire economic and social consequences (Jordan, 1976). American trypanosomiasis, endemic in several South American countries is caused by *Trypanosoma cruzi*, and transmitted by Triatominae bugs (Lidani et al., 2019).

Woody vegetation in rural areas, heat and humidity favor the breeding of the tsetse insect vector. An infected fly bite of host skin intradermally inoculates the infective, metacyclic trypomastigotes stage. Proliferation occurs by binary fission accompanied with changes to a long, slender form, and acquisition of a coat of around 10 million molecules of identical, but variant, surface glycoproteins (VSG), which shield numerous membrane-associated transport proteins, necessary adaptations to residence in the bloodstream in close contact to the host immune effectors. The VSG coat protects the parasite from the human plasma lytic factors, a combination of apolipoprotein L1 and haptoglobin-related protein (Vanhamme and Pays, 2004; Brun et al., 2010). The proliferative, slender blood-stage trypomastigotes are observed during the onset of parasitaemia in blood, lymph, and spinal fluid. They change to non-proliferative stumpy forms, a preadaptation to the procyclic stages, which access the tsetse fly midgut with a blood meal, exchange their VSG coat for procyclic stage-specific, acidic repetitive proteins, the procyclins, and proliferate, totally resistant to proteolytic enzymes. The parasites migrate to the salivary gland. The forms generated there, the epimastigotes, elaborate the undulating flagellar membrane, further multiply, and are released into the salivary gland lumen as metacyclic trypomastigotes, in preparation for transmitting the infection to a new host (Despommier et al., 2005).

Local reactions in humans at the site of tsetse fly bites are associated with lymphadenopathy. Proliferation and dissemination of trypomastigotes in blood and lymph cause headaches, fever, general weakness, and joints pain and stiffness. Parasites that cross the blood-brain barrier and migrate to the central nervous system induce neurological changes, predominantly sleep disorder (hence the name “sleeping sickness”), deep sensory disturbances, abnormal tone and mobility, ataxia, psychiatric disorders, seizures, toxemia, coma and ultimately death. In the case of *T.b. rhodesiense*-mediated human African trypanosomiasis (HAT), the disease is acute, lasting from a few weeks to several months while in *T.b. gambiense* infections the disease is chronic, generally progressing slowly over several years (WHO, 2019).

Diagnosis. Relies in the laboratory on blood smear examination (Chappuis et al., 2005a).

Treatment agents. Only five drugs are registered for HAT treatment (Steverding, 2010). The current first choices for early stages are suramin, and pentamidine, (Brun et al., 2010; De Koning, 2020). Suramin, a sulfated naphthaylamine introduced a century ago in 1920, is endocytosed in trypanosomes via binding to an invariant VSG, inhibits cytokinesis, and additionally interferes with trypanosome respiration and glycolysis, leading to cellular ATP collapse (Thomas et al., 2018; Wiedemar et al., 2020; Zoltner et al., 2020). Besides severe side-effects, its use is cumbersome as it must be intravenously injected at a dose of 20 mg/kg body weight 5 times a day for 5–7 days. Suramin central benzene ring tightly binds to a VSG, VSG_{sur}, preventing its endocytosis-mediated cellular uptake and leading to a resistance phenotype (Zeelen et al., 2021). Pentamidine, an aromatic diamidine, is endocytosed by the trypanosomes via binding to the aquaglyceroporin AQP2, accesses ribosomal RNA, inhibits protein and nucleic acids synthesis, and leads to progressive loss of kinetoplast DNA, disruption of mitochondrial membrane potential, and eventually parasite death (Thomas et al., 2018). However, it induces adverse reactions and is difficult to administer (Brun et al., 2010). Melarsoprol, an organoarsenic compound, affects *T.b. rhodesiensis*, entering via an adenosine transporter and AQP2, forming a stable adduct with the antioxidant, trypanothione, and leading to mitosis inhibition. Both melarsoprol and an α -difluoromethylornithine, eflornithine, are recommended for second-stage HAT caused by *T.b. gambiense*. Drug adverse reactions are frequent and the difficulty of administration was not circumvented (Chappuis et al., 2005b; Babokhov et al., 2013; Thomas et al., 2018). Eflornithine is commonly given in combination with nifurtimox, a nitrofurant antibiotic, which reduces the treatment time to 7 days of eflornithine infusions plus 10 days of oral nifurtimox tablets (Babokhov et al., 2013; De Koning, 2020).

A new oral drug candidate, acoziborole, an oxaborole, has shown promising results in pre-clinical and phase I/II clinical studies, and it is currently under phase III studies for single oral dose, for both disease stages. It displays potent trypanocidal activity, likely dependent on boron atom in the heterocyclic core structure (Jacobs et al., 2011), and its single oral dosing would circumvent existing therapies limited effectiveness and safety profile, and difficult treatment regimens. However, trypanosome resistance to the drug is already emerging (Dickie et al., 2020). A new 2-substituted 5-nitroimidazole drug, fexinidazole, has been developed and tested in clinical trials II/III to be used for oral, short course, safe, and effective treatment of HAT (Torreale et al., 2010; Kaiser et al., 2011; Tweats et al., 2012; Tarral et al., 2014). Phase 3 evaluation is ongoing in the Democratic Republic of the Congo and Guinea, and approval has been obtained from European Medicines Agency (EMA) in 2018, facilitating application in endemic countries (Deeks, 2019; Fairlamb, 2019; Dickie et al., 2020).

Vaccines. There is currently no vaccine and none is expected in a near future. The main reason is that the VSG coat of blood trypomastigotes is immunogenic, inducing a plethora of specific antibodies that may bind to the parasite and mediate its death via complement-dependent killing or antibody-dependent cell-mediated cytotoxicity (ADCC). However, trypanosomes possess hundreds of VSG genes, with only a single one at a given time expressing millions of identical molecules. Repressing an active and activating a previously silent expression site leads to VSG continuous and uninterrupted variability in sequences and linear and conformational epitopes, rendering the infection- or vaccine-induced antibodies harmless (Baral, 2010; Onyilagha and Uzonna, 2019).

American trypanosomiasis (Chagas disease)

Life cycle. Chagas disease is named in honor of the discoverer of its etiological agent and insect vector in 1909, the Brazilian physician and researcher, Carlos Chagas. Chagas disease constitutes one of the main public health problems in Latin America. About 6 to 14 million people in endemic areas of 21 Latin American countries are estimated to be infected with *Trypanosoma cruzi*, the parasite that causes Chagas disease (Carod-Artal, 2013). The disease is vector-borne as it is mostly transmitted to humans by contact with feces or urine of blood-sucking triatomine bugs. More than 100 species of Triatominae are capable of transmitting *T. cruzi*, notably *Triatoma infestans* and *T. dimidiata* that are widely distributed in the Americas (Lidani et al., 2019). The infective *T. cruzi* stage is not transmitted in the host blood. The epimastigotes, the proliferating stage in the insect vector intestine, do not migrate to the salivary glands. The parasites differentiate into infective metacyclic trypomastigotes in the hindgut. Parasite invasion of humans occurs following smearing the insect urine and feces deposited in the vicinity of the blood-sucking spot, often in the face (WHO, 2020a). Parasite replication in the human host does not occur in the circulation, but intracellularly where the parasites multiply by binary fission. The proliferative amastigotes differentiate into trypomastigotes, which are released in the circulation as blood trypomastigotes that may invade other cells or are ingested by the insect to continue the life cycle (Fig. 1).

Non vector-borne transmission includes blood transfusion, congenital and oral transmission, transplantation, and accidental infections (Carod-Artal, 2013; WHO, 2020a).

Chagas disease presents in two phases: acute and chronic. The early stage is usually asymptomatic despite that a high number of parasites circulate in the blood, but can present with fever, headache, enlarged lymph glands, pallor, muscle pain, difficulty in breathing, swelling, and abdominal or chest pain. Most acute cases resolve over a period of a few weeks or months into a subclinical chronic form of the disease ("indeterminate form"). Years or even decades after the initial infection, as the parasites remain hidden mainly in the heart and digestive muscles, 30–45% of infected persons present digestive, cardiac, circulatory and neurological serious problems (Carod-Artal, 2013; Henao-Martínez et al., 2019; Lidani et al., 2019; WHO, 2020a; Echeverría et al., 2021).

Diagnosis. Is by microscopic finding the parasite in blood smears, or detecting its DNA by polymerase chain reaction (PCR); chronic disease is diagnosed by serological tests detecting serum specific antibodies titer and isotype (Umezawa et al., 1996; Balouz et al., 2017).

Treatment agents. Chagas disease can be orally treated with oral benznidazole, a free radicals- generating antimicrobial nitroimidazole, which inhibits *T. cruzi* synthesis of DNA, RNA, and proteins (Edwards, 1993), or nifurtimox, a pro-drug activated by parasite

Fig. 1 Life cycle of *Trypanosoma cruzi*, the agent of Chagas disease. From Centers for Disease Control and Prevention.

nitroreductase for release of products toxic to mitochondrial structure and function (Thomas et al., 2018). Both medicines are nearly 100% effective in curing the disease if given for 30 to 60 days, soon after infection at the onset of the acute phase. Treatment is also recommended during the chronic phase, even if incapable of producing parasitological cure, because it reduces or delays worsening of the clinical condition of the patient. Adverse side reactions are common and include dermatitis, anorexia, weight loss, nausea, vomiting, and insomnia, but resolve with time (Castro et al., 2006). Fexinidazole could be considered for treatment of *T. cruzi* infection resistant to benznidazole and nifurtimox (Bahia et al., 2012). Enhancement of trypanosome cure was achieved upon combining benznidazole with curcumin (Novaes et al., 2016), or the essential oils of *Syzygium aromaticum* (Zanusso Junior et al., 2018), clove (*Syzygium aromaticum*) or ginger (*Zingiber officinale*), which have demonstrated suppression of parasitemia in Swiss mice treated for 20 consecutive days following oral administration of 10,000 *T. cruzi* blood trypomastigotes (Sarto et al., 2021). Nanocarrier-based delivery systems, notably liposomes, micelles, nanoemulsions, polymeric and non-polymeric nanoparticles are now considered for reduction of toxicity, and increase of the efficacy and bioavailability of anti-Chagas disease drugs (Quijia Quezada et al., 2019).

Vaccines. Live, attenuated *T. cruzi* parasites likely induce powerful protection, but present serious safety issues, which were attempted to be resolved via use of gene-deleted live parasites (Sánchez-Valdéz et al., 2015). Sub-unit candidate vaccines were selected among which *T. cruzi* flagellar pocket calcium-binding protein (Biter et al., 2018), and 80 kDa prolyl oligopeptidase (Bivona et al., 2018) elicited powerful type 1-related cytokines and antibodies production, and improved survival and physiological and immunological parameters in immunized mice. Recently, Traspain, based on B- and T-cell epitopes of key parasitic protein targets: cruzipain (Cz), amastigote surface protein 2 (ASP2), and a selected region of trans-sialidase, was assessed for immunogenicity and protective capacity in mice. The chimeric antigen in a DNA construct was used for primary oral immunization of male and female mice followed by intranasal protein-boost. Oral immunization was opted for because the oral route of Chagas disease transmission results in a higher mortality rate of 8–35% than is generally observed by vector transmission which is <5–10% (Antunes et al., 2019). Immune responses were characterized by increase in spleen cells augmented secretion of interferon (IFN)- γ and interleukin (IL)-17 as compared to unimmunized mice, associated with control of challenge parasitaemia (Alberti et al., 2020).

Despite considerable efforts aiming to characterize immune correlates of protection, select potential vaccine candidates, suitable adjuvants (Rios et al., 2019), and consideration of the use of plants as immunogens production platform and delivery system (Ramos-Vega et al., 2021), no vaccine has currently reached phase 1 trials (Bivona et al., 2020).

Leishmaniasis

Life cycle. Leishmaniasis, an insect-borne disease prevalent in tropics and subtropics regions, threatens over 150 million people worldwide (Kaye and Scott, 2011). The vector is a minuscule fly, the female sand-fly of the genus *Phlebotomus*. It transmits the promastigote stage of the obligate intracellular trypanosomatid protozoan of the genus *Leishmania* from host to host via skin biting and blood sucking. Human infection is caused by more than 20 morphologically indistinguishable leishmania species (Family Trypanosomatidae, Sub-Family Leishmaniinae, Clade Leishmaniatae), notably *Leishmania donovani*, *L. infantum* = *L. chagasi*, *L. mexicana*, *L. amazonensis*, *L. venezuelensis*, *L. tropica*, *L. major*, *L. aethiopica*; and *L. [V.] braziliensis*. Promastigotes are engulfed by phagocytes of the skin and other tissues, transform into amastigotes, and multiply by binary fission. *Leishmania* parasites survive and multiply undamaged in the different phagocyte populations, neutrophils, monocytes, macrophages, dendritic cells, via controlling phagosome biogenesis, acidification, and maturation, and securing the cell iron resources (Kaye and Scott, 2011). Infected cells rupture when too many amastigotes are present, allowing reinfection of resident phagocytes and distribution to other phagocytes in various tissues, including blood monocytes, which are the source of sand fly infection during a blood meal. The ingested amastigotes invade cells of the insect gut, replicate and differentiate into promastigotes, and migrate to the proboscis to continue the life cycle in the mammalian host (Kaye and Scott, 2011). The infection causes serious skin sores that may evolve in indelible disfiguring ulcers and scars characterizing cutaneous leishmaniasis. An estimated 12 million people are currently infected and about 2 million new cases occur yearly, resulting in about 50,000 deaths each year, notably in Afghanistan, Pakistan, Iran, Iraq, the Syrian Arab Republic, Tunisia, Algeria, Bolivia, Brazil, and Colombia (Ikeogu et al., 2020). Around 235,000 cases were reported in Brazil from 2007 to 2017, with preponderance associated with male gender, age range of 30–60 years, agricultural-related activities, and high relative humidity (Oliveira et al., 2021).

The life threatening form is visceral leishmaniasis (known as kala-azar), which may develop months or years of the sandfly bite, presenting with fever, weight loss, spleno- and hepatomegaly, anemia, leukopenia, and thrombocytopenia. The symptoms reflect parasite invasion of the phagocytes of liver, spleen, and blood. Visceral leishmaniasis is endemic in India, Bangladesh, Nepal, Sudan, Ethiopia, Somalia, Kenya, Iraq and Brazil. Mucocutaneous leishmaniasis leads to partial or total destruction of mucous membranes of the nose, mouth and throat. Over 90% of mucocutaneous leishmaniasis cases occur in Bolivia, Brazil, Ethiopia and Peru. Of note, beside humans, around 70 animal species have been found as natural reservoir hosts of *Leishmania* parasites (WHO, 2010; Okwor and Uzonna, 2016; Ghorbani and Farhoudi, 2017).

Diagnosis. Light microscopic examination of skin tissue or bone marrow cells (Fig. 2) is used to confirm cutaneous and visceral leishmaniasis, respectively, as the parasite is intracellularly obligate. Serological and molecular tests are available in modern settings and laboratories; however they do cross-react with other protozoa and their sensitivity changes according to the clinical form of the disease (de Brito et al., 2020).

Treatment agents. Leishmaniasis is treatable and curable. But the available drugs show several adverse reactions. Pentavalent antimonials are administered intramuscularly for visceral leishmaniasis and intralesionally for the treatment of cutaneous

Fig. 2 Light-microscopic examination of a stained bone marrow specimen from a patient with visceral leishmaniasis, showing a macrophage (note large nucleus, red arrow) containing intracytoplasmic multiple *Leishmania amastigotes* (gray arrow). Visualization of the kinetoplast (black arrow) ascertains leishmaniasis diagnosis. Credit: CDC/DPDx.

leishmaniasis, 20 mg/kg body weight daily for 28–30 days. Side effects are common and include anorexia, vomiting, nausea, abdominal pain, malaise, myalgia, arthralgia, headache, and lethargy, but the overall cure rate is >90%. Amphotericin B a polyene antibiotic given daily or on alternate days by intravenous infusion in 5% dextrose of 0.75–1.0 mg/kg per day for 15–20 days was 99% effective in India. Infusion reactions, including higher fever, rigor and chills, are common. Lipid formulations, liposomal amphotericin B, amphotericin B lipid complex and amphotericin B colloidal dispersion, are as effective as amphotericin B deoxycholate, but significantly less toxic. Intramuscularly or intravenously administered paromomycin, pentamidine isethionate, and miltefosine have also shown efficacy, as well as, adverse reactions (Croft and Coombs, 2003; Ghorbani and Farhoudi, 2017). These drugs predominantly disrupt parasite membrane, and prevent protein synthesis, among others.

Vaccines. The development of a vaccine will benefit an estimated 350 million people who are at risk of developing the disease worldwide (Gillespie et al., 2016; Okwor and Uzonna, 2016). No human vaccine is currently licensed against visceral or cutaneous leishmaniasis. Leishmaniasis vaccination started with the use of killed or live-attenuated parasites, which were substituted by second-generation subunit or recombinant DNA and protein vaccines (Moafi et al., 2019). An amastigote-specific antigen (A2) that contains immunogenic epitopes for CD4+ T helper (Th) cells and CD8+ cytotoxic T lymphocyte (CTL) epitopes was combined with saponin, alum and IL-12, or expressed by attenuated adenovirus, and shown to be protective in mice, dogs and nonhuman-primates (Fernandes et al., 2012). Currently, there is one live vaccine for humans licensed in Uzbekistan, and four licensed veterinary vaccines against visceral leishmaniasis: Leishmune[®], CaniLeish[®], Leishtec[®] and Letifend[®] that induced 60–80% protection (Moafi et al., 2019; Palatnik-de-Sousa and Nico, 2020). A human vaccine based on a mixture of nucleoside hydrolase NH36 of *Leishmania* (*L.*) *donovani*, the main antigen of the Leishmune[®] vaccine and the sterol 24-c-methyltransferase (SMT) from *L. (L.) infantum* has reached Phase I clinical trial (Palatnik-de-Sousa, 2019; Palatnik-de-Sousa and Nico, 2020). The vaccine induced high levels of IFN- γ , tumor necrosis factor- α (TNF- α), IL-2, IL-5, and IL-10 in healthy volunteers residing in a non-endemic country (USA), and was considered safe and well-tolerated (<https://clinicaltrials.gov/ct2/show/NCT01751048>).

Numerous studies examined the efficacy of peptide vaccines derived from *L. major*, *L. Mexicana*, and *L. amazonensis* against cutaneous, and *L. donovani* and *L. infantum* for protection against visceral leishmaniasis (reviewed in de Brito et al., 2018). The commonest approach was the selection of parasite peptides containing T and B cell epitopes. A most interesting strategy involving sequencing, mass spectrometry, and bioinformatics analyses of *Leishmania*-derived peptides associated with HLA class I and class II molecules on the surface of infected human macrophages was apparently not adopted (Kote et al., 2020). A different strategy targeted a sandfly salivary antigen (of 15 kDa) that facilitates *Leishmania* infection of the host for use as an adjuvant. Immune responses to vaccination with the insect salivary antigen impeded the ability of the parasite to infect its host, yielding protection against initiation of infection (Chen et al., 2020). The insect salivary antigen combined with the *L. donovani* nucleoside hydrolase, NH36, is now under development as a potential leishmaniasis vaccine (Chen et al., 2020; Liu et al., 2021).

Malaria

Life cycle. Malaria is an insect (female mosquito of the genus *Anopheles*)-borne severe disease that primarily affects humans. Infection with protozoans of the *Plasmodium* group causes symptoms that typically include fever, chills, tiredness, vomiting, and headaches. In severe cases, it can cause seizures, coma, and death. The disease is widespread in the tropical and subtropical regions around the equator. This includes much of sub-Saharan Africa, Asia, and Latin America. Five species of this single-celled microorganism can infect humans. Most deaths are caused by *Plasmodium falciparum*, which caused 99.7% of estimated malaria cases in sub-Saharan Africa, 71% of cases in the Eastern Mediterranean, 50% of cases in South-East Asia Region, and 65% in the Western Pacific. *Plasmodium vivax* is the predominant parasite in Latin America, representing 75% of malaria cases but like *P. ovale*, and *P. malariae* cause a milder form of malaria (WHO, 2020b; Laurens, 2020). In 2018 there were 228 million cases of malaria worldwide resulting in an estimated 405,000 deaths. In 2019, there were an estimated 229 million cases of malaria worldwide, and the number of malaria deaths stood at 409,000, meaning one million individuals are infected each year (WHO, 2018, 2020c). Children aged under 5 years are the most vulnerable group affected by malaria; in 2019, they accounted for 67% (274,000) of all malaria deaths worldwide. Approximately 93% of the cases and 94% of deaths occurred in Africa. Malaria is commonly associated with poverty and has a significant negative effect on economic development. In Africa, it is estimated to result in losses of 12 billion US \$ a year due to increased healthcare costs, lost ability to work, and adverse effects on tourism (Bokhari et al., 2007; WHO, 2012).

The classic symptom of malaria is paroxysm—a cyclical occurrence of sudden coldness followed by shivering and then fever and sweating, occurring every 2 days (tertian fever) in *P. vivax* and *P. ovale* infections, and every 3 days (quartan fever) for *P. malariae*. Severe malaria is usually caused by *P. falciparum* (often referred to as falciparum malaria), and elicits recurrent fever every 36–48 h, or a less pronounced and almost continuous fever. Symptoms of falciparum malaria arise 9–30 days after infection. Individuals with cerebral malaria frequently exhibit neurological symptoms, including abnormal posturing, seizures, or coma (Beare et al., 2011; Bartoloni and Zammarchi, 2012; Ponsford et al., 2012; Laurens, 2020).

Symptoms of malaria can recur after varying symptom-free periods. Depending upon the cause, recurrence can be classified as either recrudescence, relapse, or reinfection. Recrudescence is when symptoms return after a symptom-free period. It is caused by parasites surviving in the blood as a result of inadequate or ineffective treatment. Relapse is when symptoms reappear after the parasites have been eliminated from the blood but persist as dormant hypnozoites in liver cells. Reinfection cannot readily be distinguished from recrudescence, although recurrence of infection within 2 weeks of treatment for the initial infection is typically attributed to treatment failure (Markus, 2017, 2018, 2020). People may develop some immunity when exposed to frequent infections (Tran et al., 2012).

Fig. 3 Malarial life cycle in the mosquito and mammal (left and right panel, respectively). Ma gamet = male gametocyte. Modified from Open Course Ware.

Female *Anopheles* mosquito is the definitive host. A mosquito takes a blood meal from an infected human, taking in *Plasmodia* oocysts, and male and female gametocytes which are in the blood. The male and female gametocytes mature in the mosquito gut, fuse and form an *ookinete*—a fertilized, motile zygote. Ookinetes develop into new sporozoites that migrate to the insect's salivary glands, ready to infect a new vertebrate host (Fig. 3) (Siciliano et al., 2020).

When an infected mosquito takes a blood meal of the intermediate host, sporozoites in the mosquito's saliva are deposited in the skin dermis and move randomly for 1–3 h until they contact the endothelium of lymphatic or blood capillary. Sporozoites have to traverse epithelial cells and cross the endothelial barrier to access the blood stream. Sporozoites are rapidly carried to the liver sinusoids and invade hepatocytes, protecting themselves within parasitophorous vacuoles. Sporozoites remain quiescent for a while as hypnozoites (hepatic dormancy phase, notably *P. vivax* and *P. ovale*) before replicating asexually and asymptotically for a period of 8–30 days (tissue schizogony), producing thousands of schizonts that differentiate into merozoites. Following hepatocyte rupture, merozoites escape, wrapped in the cell membrane of their host liver cell, into the blood to begin the erythrocytic stage of the life cycle. Asexual multiplication cycles (blood schizogony) produce multinucleated forms, called schizonts, which undergo segmentation to form daughter merozoites, at which point the red blood cells burst and merozoites invade the blood. Waves of fever arise from simultaneous waves of merozoites escaping and infecting red blood cells. Numerous merozoites develop into immature gametocytes, which are the precursors of male and female gametes (Tan and Blackman, 2021).

Diagnosis. Malaria is typically diagnosed by the microscopic examination of stained films of peripheral blood. Standard procedures for the preparation, staining and microscopic examination of blood films for malaria parasites were recently presented (Dhorda et al., 2020). Malaria antigen detection with multiple antigens-based rapid diagnostic tests is widely used to diagnose malaria and estimate prevalence (Jang et al., 2020). Methods that use PCR to detect the parasite DNA extracted from blood spots or whole blood samples have been developed, but are not widely used in areas where malaria is common due to their cost and complexity (Srisutham et al., 2020; Mahittikorn et al., 2021). Combination of microscopy, rapid antigen-based detection test, and PCR achieves 100% specificity and sensitivity (Kotepui et al., 2020).

Treatment agents. Malaria is preventable and curable. The risk of disease can be reduced by preventing mosquito bites through the use of insecticides integrated into bednets and insect repellents or with mosquito-control measures such as spraying insecticides, and draining standing water. In 2019, an estimated 46% of all people at risk of malaria in Africa were protected by an insecticide-treated net, compared to 2% in 2000. Indoor residual spraying (IRS) with insecticides is another powerful way to

rapidly reduce malaria transmission (World Health Organization, 2020b; Bath et al., 2021). Anopheles mosquitoes resistance to pyrethroid insecticides compromises malaria control and elimination (WHO, 2012; Mnzava et al., 2015; Moyes et al., 2020).

The recommended treatment for malaria is a combination of antimalarial medications that include artemisinin, mefloquine, lumefantrine, or sulfadoxine/pyrimethamine (van der Pluijm et al., 2020). Unfortunately artemisinin resistance in *P. falciparum* is emerging, and is now prevalent across the Greater Mekong subregion (Imwong et al., 2017, 2020). The risk of spreading artemisinin-resistant parasites from the Greater Mekong subregion to Africa, as happened in the 1980s with chloroquine and pyrimethamine resistance, is a major concern, which appears to have already materialized in Burkina Faso (Gansané et al., 2021). Quinine, along with doxycycline, may be used if artemisinin is not available. It must be noted, however, that chloroquine-resistant *P. falciparum* has spread to most malarial areas (Ménard and Dondorp, 2017; Ménard and Mayor, 2020). Since 2012, WHO has recommended seasonal malaria chemoprevention as an additional malaria prevention strategy for areas of the Sahel sub-region of Africa (WHO, 2020b). The strategy involves the administration of monthly courses of amodiaquine plus sulfadoxine-pyrimethamine to all children less than 5 years of age during the high transmission season. Prophylactic activity may certainly be achieved and is of great importance. Yet, the strategy of mass drug administration definitely increases the risk of parasite resistance to the used drugs.

The risk of parasite resistance to commonly used drugs compels the search for alternative medicines. Novel compounds that possess different modes of action or novel modes of inhibition of known targets are therefore urgently needed to circumvent antimalarial drug resistance and continue treatment efficacy (Yang et al., 2021). Recently, several benzimidazole derivatives displayed transmission-blocking potential and activity against multiple stages of *Plasmodium* parasites (Leshabane et al., 2021). Of importance is to resort to extracts and derivatives of plants used in traditional medicine (Lemma et al., 2017; Pan et al., 2018), especially that the current antimalarial drug of choice artemisinin was originally obtained from the leaves of *Artemisia annua* L (Tu, 2011). Thus, remarkable antiparasmodial in vitro activity was shown for methanol, aqueous or alkaloids extracts of *Terminalia avicenioides*, *T. mantaly*, *T. superba*, *T. albidia*, *Combretum collinum* and *Ficus capraefolia* (Sanon et al., 2013; Mbouna et al., 2018; Camara et al., 2019). Recently, the benefits of marine natural products (Goto et al., 2021) and sponges metabolites, notably alkaloids, terpenoids, polyketides endoperoxides and glycosphingolipids in malaria treatment were reviewed (Aguar et al., 2021).

Vaccines. As of 2020, there is one vaccine, RTS,S/AS01 (RTS/S), based on *P. falciparum* pre-erythrocytic stage circumsporozoite protein, which has been shown to reduce the risk of malaria by about 40% in children in Africa (WHO, 2020d). The vaccine is a recombinant protein consisting of immunodominant B cell (19 NANP of the 37–44 NANP amino acid repeat sequences in the central region, R) and T cell (the polymorphic carboxy-terminal region, T) epitopes, coexpressed with hepatitis B surface antigen (S), and formulated with the AS01 adjuvant (S) (Pance, 2019). It shows efficacy in control of *P. falciparum* but is ineffective against *P. vivax* (Laurens, 2020). The vaccine is administered as primary three-dose series with a fourth dose given approximately 18 months later. Significant efficacy against severe malaria was noted in young infants or children who did receive a booster dose of the vaccine. Yet, only a substantial reduction in the number of cases of clinical malaria was observed in children who did not receive the booster dose. Unfortunately, the efficacy of RTS,S/AS01 against clinical and severe malaria decreased over time since vaccination (Olotu et al., 2016; Vandoolaeghe and Schuerman, 2018; Bell et al., 2020; Keating, 2020). Additionally, in-depth safety study was conducted in seven sub-Saharan countries, Burkina Faso, Ghana, Gabon, Kenya, Tanzania, Malawi, and Mozambique. The results based on 8922 children (enrolled at 5–17 months) and 6537 infants (enrolled at 6–12 weeks) who were randomized in three groups to receive 4 doses of RTS,S/AS01, non-malaria control vaccine, or 3 RTS,S/AS01 doses plus control challenged the RTS,S/AS01 benefit versus risk profile in real-life settings (Guerra Mendoza et al., 2019).

Children given the RTS/s vaccine showed increase in serum levels of IgG and IgA to all circumsporozoite proteins, and numerous vaccine-unrelated *P. falciparum* antigens, i.e., vaccine-specific and non-specific antibodies, with no statistically significant association with protection (Dobaño et al., 2019; Suau et al., 2021). Likewise, associations between protection and levels of vaccine-specific CD4⁺ T cells and IFN- γ have been identified, but not consistently (Moris et al., 2018).

Immune responses to RTS vaccine essentially target the sporozoites delivered by the mosquito into the blood stream. These sporozoites rapidly invade the liver cells, leaving a narrow window for specific antibodies to control the infection (Rogers et al., 2021). Indeed, care in rational selection of target vaccine antigens should be exercised before embarking in human trials, and first and foremost before contemplating use of controversial techniques to target afflicted infants and very young children (Mahase, 2021). A most commendable example has recently been given. Antibodies specific for the *P. falciparum* protein PF3D7_1021800 were previously associated with human protection against malaria, leading to an interest in PF3D7_1021800 as a candidate vaccine antigen. Antibodies to the protein were reported to inhibit schizont egress, resulting in it being named schizont egress antigen-1 (SEA1). It was recently shown that SEA1 localizes in dividing parasite nuclei and is necessary for the correct segregation of replicated DNA into individual daughter merozoites, but its localization and function preclude it to be a target for protective antibodies (Perrin et al., 2021).

Of note, numerous vaccine antigens have been selected targeting the sporozoites to prevent establishment of infection, among which the full length circumsporozoite protein and the thrombospondin-related anonymous protein. Many have reached different phases of clinical trials (Duffy et al., 2012; Pance, 2020; Friedman-Klabanoff et al., 2021). However, none has led to promising results regarding the effective control of the disease (Molina-Franky et al., 2020). Surface membrane antigens of merozoites, notably the invasion protein AMA1 (Sirima et al., 2017; França et al., 2021), and the parasite antigens embedded in infected erythrocytes membranes, such as *P. falciparum* Erythrocyte Membrane Protein-1 (PfEMP1), were also considered promising vaccines for inducing immune responses capable of interfering with red blood cells invasion, destruction, and the waves of disease (Frimpong et al., 2018). Vaccines targeting the gametocytes, among which the antigens Pfs230C and Pfs48/45, showed efficacy in blocking transmission from humans to the mosquito justifying the possibility of reaching different phases of clinical trials, but showed limited protection (Pance, 2020).

Another critical concern was raised regarding the degree of selected vaccine antigens genetic variability among *Plasmodium* species and strains (Pance, 2020). It is not understood how the RTS/S vaccine has progressed that far knowing the gene encoding *P. falciparum* circumsporozoite protein central and carboxy terminal regions harbors great genetic diversity, the low prevalence of the vaccine malaria haplotype in Africa and Asia, and the antibody efficacy decrease with any amino acid difference (Pance, 2019). Vaccine candidates designed to target surface proteins such as AMA1 and PfEMP1 are highly immunogenic but extremely polymorphic (Frimpong et al., 2018; Bittencourt et al., 2020). In that respect, the sequencing of *P. falciparum* whole genome greatly assisted researchers in the selection of potentially protective candidate vaccines, which are highly conserved among *Plasmodium* species and strains (Gardner et al., 2002). A prominent example is Pfs25 which high conservation and effectiveness in inducing transmission-blocking antibodies promote it to the status of a leading vaccine candidate (Juliano et al., 2016; Pance, 2020).

Toxoplasmosis

Life cycle. Toxoplasmosis is a food-borne disease that results from infection with *Toxoplasma gondii* the world's most common parasite, with 40 million in the most developed country, the USA, carrying the parasite (Jones and Dubey, 2012; Jones et al., 2014). In many areas of the world that have hot, humid climates and lower altitudes, more than 60% of some populations are infected with *T. gondii* (Saadatnia and Golkar, 2012; Heavey, 2018). Toxoplasmosis is not a person to person infectious disease. Infection usually occurs by exposure to infected cat feces, eating undercooked meat contaminated with the parasite cysts, and mother-to-child transmission during pregnancy. Most people affected never develop signs and symptoms except for persons with weakened immune systems and infants born to infected mothers. A most serious complication is stillbirth or miscarriage in women newly infected with *Toxoplasma* during or shortly before pregnancy. A small number of infants who survive are likely to be born with serious problems, notably seizures, spleno- and hepatomegaly, and eye infections. Many infected children show hearing loss, mental disability or extremely serious eye infections in their teens (Heavey, 2018).

Toxoplasma gondii is a single-celled, protozoan parasite that can orally infect virtually all warm-blooded vertebrates, especially birds, most animals, and humans. Because *T. gondii* infectious oocysts are excreted only in cat feces, wild and domestic cats are the parasite's only known definitive host. Cats become infected by eating infected rodents, birds, or raw meat. The parasites sexually reproduce in cat intestines. Fertilization of haploid macrogametes by haploid microgametes results in diploid zygotes, around which a protective wall develops, forming unsporulated oocysts that pass in the feces. Cats can shed millions of oocysts in their feces for as long as 3 weeks, especially after the first infection. Oocysts take 1–5 days to sporulate in the environment, especially in hot and humid areas. Oocytes can remain infectious for more than a year in soil or water under ambient conditions, and are infective to birds, rodents, livestock, and humans via the oral route. After an intermediate host ingests oocysts, sporozoites are liberated in the intestine where they invade enterocytes and differentiate into rapidly dividing tachyzoites. Tachyzoites are disseminated via the blood stream to all tissues, and are able to infect all nucleated cells. The immune responses trigger the conversion of tachyzoites into bradyzoites inside cysts, which form 7–10 days after infection and remain viable in multiple organs, including the central nervous system and muscles. These cysts may remain viable throughout the life of the host. Healthy immune system keeps the parasites in the body in an inactive state, providing lifelong immunity to a second infection. In humans, if an underlying disease, chemotherapy, or immunosuppressive medications weaken the immune system, the infection can be reactivated, leading to serious complications (Dubey, 1998; Deng et al., 2020).

Diagnosis. Toxoplasmosis is efficiently diagnosed using serological tests that determine the titer and isotype of anti *T. gondii* specific serum antibodies (Saadatnia and Golkar, 2012; Heavey, 2018). Several fully automated immunoassays are commercially available, notably Architect i4000ISR; Immulite 2000 Xpi, Siemens; Liaison, DiaSorin; and Cobas e601, Roche, and manual immunoassays are easy to devise. However, anti-Toxoplasma IgG quantitative immunoassays still lack standardization (Zhang et al., 2017). Besides serological tests, diagnosis for immunocompromised patients is usually done using PCR, and histological analysis. For congenital cases, definitive diagnosis is through direct PCR detection of the organism from amniotic fluid samples (Ybañez et al., 2020).

Treatment agents. Most healthy people recover from toxoplasmosis without treatment. Persons who show complications must receive long time treatment with combination of pyrimethamine sulfadiazine, folic acid inhibitors, which efficiently kill the replicating tachyzoite stage of the parasite, but show limited efficacy against the slow dividing bradyzoites (Montoya and Liesenfeld, 2004). The parasites are not completely eliminated because of their location within tissue cells in a quiescent phase. Hence, there currently is no approved therapy that can eradicate *T. gondii* tissue cysts, which are responsible for chronic infection (Dunay et al., 2018; Montazeri et al., 2018). Additionally, *folinic acid* is recommended as a remedy against the drugs toxic impact. Bisphenol Z derivatives were recently found to disrupt mitochondrial function and inhibit parasite replication in vitro; in vivo efficacy was not yet assayed (Hatton et al., 2020). Recently, combinations of pyrimethamine, clindamycin, guanabenz, and endochin-like quinolones (ELQs) were hardly able to eradicate brain cysts of *T. gondii*-infected laboratory mice (Doggett et al., 2020).

Vaccines. Thorough guidelines have been published by the Centers for Disease Control and Prevention (<https://www.cdc.gov/parasites/toxoplasmosis/prevent.html>), as there is no vaccine for human *T. gondii* (Singh et al., 2020). Vaccine development over three decades focused on prevention of tissue cyst development and vertical transmission in livestock and cats (Wang et al., 2019). Cysts shield parasites from immune detection and responses, and are unaffected by the immunity elicited by the available veterinary vaccines (Bonačić Marinović et al., 2019; Ramakrishnan et al., 2019). Immunoinformatic approaches (Asghari et al., 2021), and development of protocols for differentiation of embryonic and pluripotent stem cells into a variety of cell types and organoids (Pance, 2021) might overcome the hurdles of devising vaccines against the cyst-shielded *T. gondii*.

Parasitic nematodes (eukaryotes)

Filariasis

Filariasis is again an insect-borne parasitic disease, caused by infection with roundworms of the Filarioidea type that are spread by blood-feeding insects such as *Aedes*, *Anopheles*, and *Culex* mosquitoes (lymphatic filariasis), and black flies of the family Simuliidae (onchocerciasis). These parasites exist in the wild in subtropical parts of southern Asia, Africa, the South Pacific, and parts of South America, and inhabit the human lymphatic system or subcutaneous tissues (Fig. 4) (Klion, 2019; Bizhani et al., 2021).

Lymphatic filariasis

Life cycle. Lymphatic filariasis is a disease of the lymphatic system, caused by the microscopic nematodes, *Wuchereria bancrofti* (the only known etiologic agent in Africa), *Brugia malayi*, and *B. timori* (found only in Indonesia), and transmitted in humans following a blood meal from an infected mosquito. Lymphatic filariasis affects over 120 million people with about 40 million disfigured and incapacitated by the disease throughout the tropics and sub-tropics of Africa, Asia, the Western Pacific, and parts of the Caribbean and South America, namely Haiti, the Dominican Republic, Guyana and Brazil. Around 893 million people in 52 countries worldwide remain threatened by lymphatic filariasis and require preventive chemotherapy to stop the spread of this vicious parasitic infection (Klion, 2019; Mathew et al., 2020; Bizhani et al., 2021).

The organisms, male and female stage L3 larvae, migrate to the lymphatic vessels and lymph nodes in the legs, feet, arms, breast, and scrotum. Over 6 months or more, the larvae molt through two more stages maturing into female of 80–100 mm in length and 100–300 µm in diameter, and male worms of 40 mm by 100 µm about half the size of females. Mating produces thousands of microfilariae, which are sheathed and thread-like, 244–296 µm by 7.5–10 µm. The millions of produced microfilariae and the immune responses they generate elicit inflammation and clogging of the lymph vessels, edema and fibrosis of surrounding tissues, organ swelling, thickening of overlying skin, symptoms of the disease known as elephantiasis, surprisingly enough in percentage of infected persons, and years after infection. The majority of infections are asymptomatic. These asymptomatic infections still cause chronic damage to the lymphatic system with clinical manifestations, such as acute adenolymphangitis, filarial fever, and tropical pulmonary eosinophilia (Lourens and Ferrell, 2019; Zulfiqar and Malik, 2021). Additionally, all infected persons can transmit the disease, as adult worms can survive in human lymph system for up to 6 years while microfilariae move from lymph to blood, and are taken up by the intermediate vector, insects such as *Culex* and *Anopheles* during a blood meal. After ingestion, the microfilariae lose their sheaths and work their way through the wall of the midgut to reach the thoracic muscles. There the microfilariae develop into first-stage larvae and subsequently into second and third-stage larvae. The third-stage larvae migrate through the hemocoel to the mosquito's mouth parts and can infect another human when the mosquito takes a blood meal, injecting the infectious L3 larvae into the dermis layer of the skin of the final host (Fig. 4).

Of note, *Wuchereria* and *Brugia* spp., like many other species of filarial nematodes, harbor an intracellular endosymbiont, *Wolbachia*, which are vital for larval development and adult-worm fertility and survival, as *Wolbachia* is necessary for growth, fertility and viability of the nematode host, while the host supplies amino acids needed for *Wolbachia*'s development (Taylor et al., 2005; Wan Sulaiman et al., 2019; Gunderson et al., 2020; Bulman et al., 2021).

Diagnosis. Definitive diagnosis may be accomplished by identifying microfilariae in thick blood smears stained with Giemsa or hematoxylin and eosin. The microfilariae that cause lymphatic filariasis circulate in the blood at night (called nocturnal periodicity). Blood collection should be done at night to coincide with the appearance of the microfilariae. For increased sensitivity, especially in

Fig. 4 Life cycle of filarial nematodes causing lymphatic (left) and subcutaneous (right) filariasis. From Centers for Disease Control and Prevention.

Fig. 5 Drugs of choice for treatment of filariasis kill microfilariae not adult worms.

light infections, one of several concentration methods may be used. Of note, microfilariae are not detected in blood in the early phases of the infection. In such cases, serologic techniques are useful for diagnosis of lymphatic filariasis. Patients with active filarial infection typically have elevated levels of antifilarial IgG4 in the blood and these can be detected using routine assays (Wamae, 1994; Palumbo, 2008).

Treatment agents. Diethylcarbamazine citrate (DEC), Ivermectin (I), and albendazole (ALB) (Fig. 5) combination is the therapy of choice for treatment of persons diagnosed with filariasis despite it kills only the microfilariae and does not affect the adult worms (Krentel et al., 2021).

The development of the World Health Organization's Global Programme to Eliminate Lymphatic Filariasis (GPELF) is based on annual mass treatment with these drugs, aiming to reduce the level of microfilariae in the blood and thus, diminish transmission of infection (Ramzy et al., 2019; Deribe et al., 2020; Ottesen and Horton, 2020). In countries without onchocerciasis, the combination of Iv (200 µg/kg) together with DEC (6 mg/kg) and ALB (400 mg) can safely clear almost all microfilariae from the blood of infected people within a few weeks (Krentel et al., 2021). In support of the 3 drugs-combination (IDA), naive adults with *W. bancrofti* microfilaremia in Côte d'Ivoire were randomized to receive a single dose of IDA ($n = 43$) or 3 annual doses of Iv and ALB (IA) ($n = 52$) in an open-label, single-blinded trial. At 6 and 12 months post treatment, IDA was significantly ($P < 0.001$) superior to DEC-free IA in clearing microfilariae. A substantial number of persons examined 36 months post-treatment were still infected due to reinfection or the inability of the drugs combined to eliminate adult worms, which may survive in the human hosts for up to 6 years (Bjerum et al., 2020). In a similar setting, Iv plus ALB (IA) was found to be more effective than ALB alone. Indeed, repeated semiannual treatment with ALB alone was shown to be macrofilaricidal for *W. bancrofti* and leads to sustained reductions in microfilariae counts. However IA was more effective for completely clearing microfilariae than ALB 400 mg or 800 mg (Ouattara et al., 2021). The safety and efficacy of mass drug treatment (MDA) with a single oral dose of IDA or DA (DEC and ALB) were recently examined in children >5 years old in India. No serious adverse reactions were recorded: only transient fever, headache and dizziness. Combination of the three drugs (IDA) was more effective for clearing microfilariae than ivermectin-free DA treatment (84% vs. 61.8%, $P < 0.001$) (Jambulingam et al., 2021).

Adult worm killing may be achieved with treatment with doxycycline (200 mg/day for 4–6 weeks), as it was shown to deplete *Wolbachia* and eventually eliminate the adult worms (Wan Sulaiman et al., 2019). In Tanzania, ultrasonography detected adult worms in only six (22%) of 27 individuals treated with doxycycline compared with 24 (88%) of 27 with placebo at 14 months after the start of treatment (Taylor et al., 2005). Recently, reports documented the threat of *Wolbachia* rebound following antibiotic treatment, likely because of the bacterial persistence in privileged sites, such as ovaries, in the filarial adult female worms (Gunderson et al., 2020), or counterintuitive response to antibiotic dose response, dubbed the "Eagle effect" (Bulman et al., 2021).

Vector control interventions conducted by other programs, particularly malaria vector control, have had a profound effect in stopping transmission in some endemic countries in the region. Physical control such as use of bed nets, sound traps, and removal of mosquito breeding or swarming sites has met with some success. Plant extracts-based and essential oil repellents, insecticides, microbes-derived toxic peptides, biological agents, and genetic modifications techniques have been widely used (Amer and Mehlhorn, 2006; Parihar et al., 2020; Lupenza et al., 2021a) especially targeting mosquitoes of the genera *Aedes*, *Anopheles*, and *Culex* (Fig. 6). Nevertheless, interruption of transmission of the infection is still not evident in numerous sub-Saharan African countries (Famakinde, 2018; Mathew et al., 2020; Yokoly et al., 2020; Lupenza et al., 2021b).

Vaccines. There is no commercially licensed prophylactic vaccine available for lymphatic filariasis (FL). With over 880 million people at risk, there is great potential for developing a vaccine for LF. An effective prophylactic vaccine should confer long-lasting and robust protective immune responses in the vaccinated individual and overcome the complex mechanisms of parasite immune evasion, especially the microfilariae sheath (Joardar et al., 2021). The most promising vaccine candidates would elicit immune responses directed against the infective or early developing larval L3 stages, the most vulnerable stage of the parasite in the mammalian host in terms of its size as well as biological requirements. After entry into the body, L3 must wade its way through the subcutaneous tissue into presumably the nearest lymphatic vessel, where it needs to rapidly metabolize, grow in size and develop and molt within about 10–12 days into L4 stage. An L3 larva-derived vaccine candidate must show considerable homology in *W. bancrofti*, *B. malayi* and *B. timori* to be useful in different settings and countries (McNulty et al., 2013). Vaccine-induced specific

Fig. 6 Aedes mosquitoes are black and have white patches. Culex and Anopheles are yellowish, but Culex stay parallel to the surface, while Anopheles mosquitoes rest at ~45 degree angle. Source: Dr. Mubarak Ali Aldoub.

antibodies, especially of the IgG1 and IgG3 isotypes, may affect L3 larvae, which are still unsheathed and can be vulnerable to ADCC (Dakshinamoorthy et al., 2013). Cell adherence to *B. malayi* L3 larvae has been demonstrated (Kalyanasundaram et al., 2020). Accordingly, vaccine candidates must be exposed on the L3 larvae surface membrane, and additionally should show low homology to corresponding human molecules and must fail to induce considerable IgE responses (Kalyanasundaram et al., 2020). Nearly all attempts to develop a vaccine against LF with a single antigen (monovalent) gave unsatisfactory results. Recently, *B. malayi* calreticulin was found to be immunogenic in *Mastomys coucha*, a permissive model for LF, but elicited partial protection (Yadav et al., 2021). A vaccine based on B-cell and T-cell epitopes derived from the aspartic protease of *B. malayi* (BmASP-1) was found to display significant humoral and cell mediated immune responses using in-silico approaches, but was not tested in vivo (Das et al., 2021). Conversely, a chimera of molecules possessing the selection criteria mentioned above was promising. The fusion of *B. malayi* heat shock protein 12.6 (H), abundant larval transcript -2 (A), and tetraspanin large extra-cellular loop (T) (Dakshinamoorthy et al., 2014), together with thioredoxin peroxidase-2 (X) in a tetravalent recombinant construct, rBmHAXT (Khatri et al., 2018) provided the highest protection levels in *Rhesus macaques*. This construct is considered a leading prophylactic vaccine formulation because it elicits high protection levels in challenged non-human primates, considered the best, if not the only, models available to study the protective potential of filarial vaccines. Of significant importance was the discovery that the multivalent recombinant construct was L3 larvicidal, microfilaricidal, and additionally impaired the fecundity of *B. malayi* adult female worms (Khatri et al., 2020). As of today, the promising rBmHAXT vaccine in conjunction with AL019 (alum plus glucopyranosyl lipid adjuvant-stable emulsion) meets various hurdles and blocks delaying or preventing preclinical and clinical trials in humans (Kalyanasundaram et al., 2020).

Onchocerciasis

Life cycle. Onchocerciasis, also known as river blindness or subcutaneous filariasis, is a disease caused by infection with the parasitic worm *Onchocerca volvulus*, transmitted by repeated bites of the vector, female black fly of the genus *Simulium* as males feed on nectar. More than 99% of 25 million people infected worldwide live in 31 countries in sub-Saharan Africa and 1% in the Arabian Peninsula, and small localities in Mexico, Colombia, Venezuela, Guatemala, and Brazil. The WHO estimates that 90 million people are at risk, with more than 99% of them in Africa. The disease is responsible for the annual loss of close to 1 million DALYs. Vision loss is estimated to affect 1.15 million people. Economic losses were estimated at 30 million US dollars (Gyasi et al., 2021).

Symptoms appear months or years after infection, due to intense inflammatory immune responses to the parasites resulting in rashes, severe itching, skin lesions, swelling and altered pigmentation, and nodules, bumps and lumps under the skin. Skin-related afflictions and damage prevail in forest areas. Some infected people develop ocular lesions which can lead to visual impairment and sometimes permanent blindness, especially in the African savanna, along flowing streams and rivers where the vector breeds, hence the name river blindness (Remme, 2004). Association between onchocerciasis and epilepsy was demonstrated (Vinkeles Melchers et al., 2018; Siewe Fodjo et al., 2020).

The prevalence of human onchocerciasis is determined by the distance between where *Simulium damnosum sensu lato* (s.l.), the main vector in Africa breed, and where people live and work, as the flies typically have an active flight range of around 15 km. Endemicity of the infection is also directly related to the abundance of the vector. Fast-flowing rivers and streams, and high levels of oxygenation needed for larval development are ecological conditions favorable for *Simulium* breeding. New vector breeding sites and seasonal changes impact the pattern of disease transmission and create public health problems. Additionally, cytogenetic differences in *S. damnosum* s.l. determine whether they transmit the savanna strain of *O. volvulus* that most often causes blindness, or the forest strain of the parasite that causes skin disease as its main pathogenicity rather than an eye disease (Cheke, 2017; Nikiéma et al., 2019; Zarroug et al., 2016, 2019).

The definitive hosts of *Onchocerca volvulus* are humans. Female blackflies taking a blood meal from an infected person ingest *O. volvulus* microfilariae. Development into infective L3 larvae that are transmitted to a different host during subsequent blood meals resembles that in lymphatic filariasis vectors (Fig. 4). Ingested microfilariae transform over 1 to 3 weeks by moving from the insect gut into the thoracic flight muscles as an L2 larval stage, develop into an infective L3 larval stage, and then migrate into the salivary gland for subsequent transmission during the next blood meal. The L3 larvae develop via L4 into adult worms, macrofilariae, in fibrous sub-cutaneous nodules, located commonly around the iliac crest, the head, and torso, in approximately

12–18 months. Adult worms live for around 10–15 years. Each nodule may contain one or two female worms and a single male that is usually smaller in size. Adult worms produce millions of microfilariae of 250–300 μm by 8 μm , which migrate through the skin, eyes, and other organs, and have a lifespan of approximately 12–15 months (Basáñez et al., 2009) (Fig. 4).

Diagnosis. Onchocerciasis diagnosis, monitoring, and evaluation are based on detection of the parasites in skin nodules, skin biopsies, or skin scrapings by light microscopy. Polymerase chain reaction techniques are increasingly used to improve sensitivity and confirm the identity and load of *O. volvulus* in residual skin snips (Lloyd et al., 2015; Thiele et al., 2016).

Treatment agents. Oral ivermectin is the drug of choice for the treatment of onchocerciasis. A dose of 150 $\mu\text{g}/\text{kg}$ is recommended once or twice a year for 10–15 years, the life span of the adult worms which continuously produce microfilariae. The treatment is accompanied by severe adverse reactions, notably headaches, myalgia, arthralgia, and neurological symptoms, in only 1:10,000 treated patients (Makenga Bof et al., 2019). Ivermectin paralyzes or kills the microfilariae but has no effects on the adult worm viability, though it reduces the fertility of female adult worm at least temporarily. Skin microfilariae are reduced by 50% in 1 day, 94% in 1 week, and 98–99% by 1–2 months, following a single dose of ivermectin (Basáñez et al., 2008; Gyasi et al., 2021). However, microfilariae repopulation of skin and eye resumes in a few months, and this is due to continuous production by the adult worm (Nikiéma et al., 2021).

Moxidectin, a member of the macrocyclic lactone family of anthelmintic drugs, was recently approved for the treatment of onchocerciasis as a microfilaricidal drug in individuals over the age of 12. In humans, a single dose of moxidectin (8 mg) appeared to be more efficacious than a single dose of ivermectin (150 $\mu\text{g}/\text{kg}$) in terms of inhibiting L3 and L4 molting, and microfilariae motility and viability (Opoku et al., 2018; Prichard and Geary, 2019; Jawahar et al., 2021).

Effective cures targeting the adult parasites (macrofilaricides) which survive and reproduce in the host for very long periods are needed (Hawryluk, 2020; Tyagi et al., 2021). Tablet doxycycline is promising in this regard, and may kill the adult worm by killing *Wolbachia*, endosymbiotic, rickettsia-like bacteria, which are crucial for the survival and fecundity of microfilariae. The recommended dose is oral 100 mg or 200 mg once daily for 6 weeks. Doxycycline can sterilize up to 90% of adult female worms and kill at least 60% adult female worms 20 months after treatment (Debrah et al., 2015; Abegunde et al., 2016; Wan Sulaiman et al., 2019). Two potential macrofilaricidal drugs, oxfendazole and emodepside are currently under clinical development (Hübner et al., 2020; Jawahar et al., 2021).

Vaccines. There is no vaccine available and it is difficult to anticipate vaccine development and progress till the commercial level targeting less than 100 million people at risk of onchocerciasis. The Onchocerciasis Vaccine for Africa (TOVA) partners 25 years efforts have been crowned by the selection of three promising candidate vaccine antigens which evoke strong protective responses capable of reducing challenge parasite burden of immunized animals by more than 90%. The selected molecules are on the surface and secretory-excretory products of L3 and L4 larvae, adult worms and/or microfilariae. Ov-CPI-2 is a cysteine protease inhibitor located at the basal layer of cuticle, Ov-Ral-2 and Ov-103 are novel, nematode-specific molecules, located in the hypodermis. The three molecules were expressed in bacterial and yeast expression systems. Combination of the antigens by either co-administration vaccine strategies, or single injections using a recombinant fusion protein vaccine induced in mice enhanced levels of protective immunity, demonstrating that the antigens could act synergistically in both systems. Only adjuvants that induced Th2 responses, as determined by cytokine profiles, were effective at enhancing the vaccine efficacy, consistent with reports showing that IL-4, IL-5, and functional eosinophils are necessary for the development of adaptive immunity in onchocerciasis. Protection in genetically diverse mice strains and humans proved to be dependent on Ov-Ral-2 and Ov-103-specific antibodies, predominantly of the IgG1 and IgG3 isotype together with neutrophils, macrophages and eosinophils (Lustigman et al., 2018; George et al., 2019; Ryan et al., 2021). TOVA aims to take at least one of these vaccine candidates through Phase I trials by 2025. Meanwhile, immuno-informatics analyses attempt to identify novel vaccine candidates in multi T and B cell epitopes- based vaccine formulation (Shey et al., 2019, 2021).

Soil-transmitted helminths (*Ancylostoma*, *Necator*, *Ascaris*)

Ancylostoma and *Necator*

Life cycle. There are no vectors or intermediate host to incriminate in transmission of infection caused by the helminth nematodes, *Ancylostoma duodenale* and *Necator americanus* in humans. Eggs in human feces hatch in humid and warm soil within 24 to 48 h releasing a first stage rhabditiform larva which molts twice to develop to an L3, 600 μm filariform, infective stage. The larvae pierce the skin of humans walking bare foot or wading in contaminated water, access the circulation, and are swept to the heart and lungs. Following rupture of the lung blood capillaries, the larvae in the parenchyma reach the trachea and pharynx. Swallowed larvae molt twice in the wall of the small intestine and mature into male and female adult worms, of 8–15 mm in length by 0.4–0.6 mm in diameter. Mated worms produce thousands of eggs daily that are released to the exterior to contaminate other individuals (Hotez et al., 2005, 2008).

Ancylostoma duodenale and *N. americanus* are common parasites with an estimated 576–740 million individuals infected, of which 80 million are severely infected, and more than 1.5 billion people, notably pre-school and school-age children, at risk in tropical and sub-tropical poor rural regions of America, Asia, and Africa (Bundy et al., 2020). Northern Africa is plagued by *A. duodenale*. The disease is characterized by malnutrition, abdominal pain, nausea, and anemia due to significant blood loss as a result of the attachment, residence, and voracious blood feeding of the worms in the small intestine. Severe anemia in young children leads to retardation in growth and cognitive functions. Hookworm-associated malnutrition and anemia severely affect pregnant women (Ness et al., 2020), and account for the loss of up to 4.1 million DALYs annually (Hotez et al., 2005, 2008; Ronquillo et al., 2019).

Diagnosis. Definitive diagnosis relies on eggs detection in stool. The eggs of *A. duodenale* and *N. americanus* are indistinguishable, colorless and transparent, oval in shape, thin-shelled, $60 \times 40 \mu\text{m}$, with a clear space between the shell and the central 4–8 blastomeres.

Treatment agents. Infection can be prevented by prohibiting defecation and walking bare foot in fields or gardens, and eating unwashed vegetables and fruits in areas where *A. duodenale* prevails. Albendazole (Fig. 5) and mebendazole are effective for treating both *A. duodenale* and *N. americanus*. Oral administration of ALB (400 mg, once daily) or mebendazole (100 mg twice daily) for 3 days are effective in cure of light and moderate infections. These benzimidazoles preferentially bind to nematode tubulin, leading to inhibition of its polymerization or assembly into microtubules, thus stopping cell division, especially in worm intestinal and tegumental cells (Bethony et al., 2006). It was recently shown that ALB is a DNA intercalator (Will Castro et al., 2021), explaining its deleterious impact on worm metabolism and survival, and severe toxicity. Successful treatment does not prevent reinfection, which is extremely high within 30–36 months of treatment, necessitating regular drug administration and emergence of the threat of parasite drug resistance (Hotez et al., 2006).

Vaccines. Currently, leading vaccine candidates are *N. americanus* aspartic protease-1 (Na-APR-1) and glutathione S-transferase-1 (Na-GST-1), enzymes involved in the digestion and detoxification of hemoglobin in the hookworm digestive tract, thereby depriving the worm of its ability to digest its blood meal. The antigens expressed in *Pichia pastoris* and adjuvanted with Alhydrogel (aluminium hydroxide gel suspension) elicited highly significant protective immunity in laboratory animals, and were safe, well-tolerated, and immunogenic in unexposed individuals (Bethony et al., 2008; Diemert et al., 2017). The recombinant vaccine candidates adjuvanted with Alhydrogel and an aqueous formulation of glucopyranosyl lipid A were administered to healthy Gabonese adults, residents of areas endemic for *N. americanus* and other helminthes. The vaccines were shown to be safe and well tolerated whether administered separately or co-administered, and resulted in significant IgG1 responses to both antigens (Adegnika et al., 2021). Of note these antigens did not elicit IgE responses, differently from Na-ASP-2 (*N. Americana* Ancylostoma secreted protein-2) hookworm vaccine, an ESP produced by infective *N. americanus* larvae upon penetration of human skin. The trials with this antigen were halted because it induced generalized urticarial reactions in previously hookworm-infected volunteers (Diemert et al., 2012; Zawawi and Else, 2020).

Hookworms' cathepsin B cysteine proteases should be developed for prophylaxis against soil-transmitted helminthes as they would induce antibodies that neutralize the catalytic activity of the hookworm antigens in the gut, resulting in reduction of the adult worms motility and viability (Noon et al., 2019). Additionally, cysteine proteases are renowned for inducing type 2 immune responses, notably IL-4, IL-5, and IL-13 cytokines and IgG1 specific antibodies, crucial and central for experimental hosts and humans acquired immunity to gastrointestinal nematodes (Grencis, 2015; Zawawi and Else, 2020).

Ascaris

Life cycle. Vectors, insects, intermediate hosts may not be held responsible for transmission of the human ascarid, *Ascaris lumbricoides*. Fertilized eggs deposited with feces in the soil contain one cell embryo that divides to give infective L3 larvae, and can survive in soil for 10 years or more. Human infection occurs following ingestion of unwashed vegetables and fruits contaminated with embryonated eggs. Excystment in the jejunum releases the larvae which penetrate the wall of the duodenum and enter the blood stream. They are swept to the liver, then the heart, and pulmonary circulation to break free in the alveoli, where they grow and molt twice over about 2–3 weeks. The larvae traverse the respiratory system to the buccal cavity to be coughed up, or swallowed, and carried back to the small intestine, residence for worm maturation, mating, and fertilization. The release of eggs by the female worm commences about 60 days after swallowing an infective egg. Adult worms are not microscopic or small as they reach up to 35 cm in length and 2–6 mm in diameter (they are roundworms). Parasite eggs are released by the thousands daily with feces to continue the life cycle and maintain transmission (Murrell et al., 1997; Deslyper et al., 2019; Holland, 2021).

An estimated 807 million–1.2 billion people in the world are infected with *A. lumbricoides* especially in poor rural and urban areas of Northern Africa and tropical and subtropical countries of Asia, Africa, and the Americas. Prevalence is particularly high in India (Christu Rajan et al., 2020) and sub-Saharan African countries (Cedric et al., 2021; El Tantawy et al., 2021; Dantie et al., 2021). Although the infection is asymptomatic, its effects may contribute to child morbidity when associated with malnutrition, pneumonia, abdominal swelling and pain, diarrhea, iron and vitamins deficiency. A most identical species *Ascaris suum*, principally infect pigs. Related ascarids of the *Toxocara* genera infect dogs, cats (Rostami et al., 2020a, b) and livestock, and increasingly threat transmission to humans, as 1.4 billion people worldwide, particularly in subtropical and tropical regions, are infected with, or exposed to *Toxocara* species (Rostami et al., 2019; Ma et al., 2020).

Diagnosis. Definitive diagnosis is via identification of fertilized eggs in feces samples by light microscopy. *Ascaris lumbricoides* eggs are round, 45–75 by 35–50 μm , thick-shelled with an external mamillated layer, and containing a developing embryo. Infection can be prevented by prohibiting defecation outdoors, especially in humid soil in gardens and fields, and thorough washing, peeling or cooking vegetables and fruits. Avoiding contact with feces-based fertilizers and sewage water is mandatory. Considerable numbers of *Ascaris* eggs were detected in sewage sludge before and after liming (treatment with 1% calcium oxide), and were not eliminated after 45 days of solar drying in summer, in a semi-arid climate (An-Nori et al., 2021).

Treatment agents. Treatment is based on albendazole and mebendazole, given orally for 1–3 days. The drugs are effective and appear to have few side effects, but must be administered regularly as they do not prevent reinfection. Moreover, it was recently reported that albendazole and mebendazole fail to entirely eliminate the worm load and recommend including ivermectin in the treatment protocol (Djune-Yemeli et al., 2020). Alarms of emerging parasite resistance to these essential medicines (Krücken et al., 2017) necessitated development of alternative treatments. Chicory (*Cichorium intybus* L.), a blue-flowered Mediterranean plant of

the daisy family, cultivated for its edible salad leaves and root, appeared promising in reduction of the gastrointestinal parasites burden in animals and humans. Chicory sesquiterpene lactones, notably 8-deoxylactucin, were shown to be the agents responsible for *A. suum* in vitro killing. Extensive chicory breeding and extraction of active compounds could assist in safe and effective control of ascarids in humans and animals (Valente et al., 2021).

Vaccines. It is difficult to elicit antibodies that may directly harm the parasite as all stages are covered with a thick cuticle, a flexible and resilient collagen-rich exoskeleton, which is synthesized five times, once in the embryo and subsequently at the end of each larval stage prior to molting (Winkfein et al., 1985). Accordingly, molecules in the epidermis beneath the cuticle may not be considered as vaccine candidates. Accordingly, it is difficult to figure out how immune responses to the *A. suum* immunodominant AS-37, mostly localized in muscle and hypodermic structures, may affect the parasite motility or survival (Versteeg et al., 2020). Larval excretory or secretory products (ESP) or extracellular vesicles may induce antibodies that activate eosinophils, mast cells, basophils, neutrophil and macrophages capable of chasing, interfering or delaying migration, and harming parasites via release of toxic molecules and inflammatory mediators (Hansen et al., 2019; Ebner et al., 2020). *Ascaris suum* ESPm As14, As16, AS24, and AS-Enol (enolase) in a recombinant form elicited type 2 cytokines, IgG and IgA specific antibodies, and variable, but significant, reduction in recovery of lung stage worms in pigs and mice (Chen et al., 2012; Wei et al., 2017; Zawawi and Else, 2020). Vaccine candidates AS14, As16, and As37 peptides containing B cell epitopes were selected and their encoding DNA sequences combined into a single chimeric gene bridged by codons for glycine-serine as linker to increase the flexibility of the chimeric protein expression into bacterial expression vector. The chimeric protein adjuvanted with monophosphoryl lipid A elicited specific IgG production and highly significant ($P < 0.0001$) reduction ($>70\%$) in challenge lung larval load in BALB/c mice (de Castro et al., 2021). *Ascaris* adult worms mouth- and intestine-derived antigens may induce antibodies able to access the parasite worm parts and intestinal mucosa, and cause significant damage (Rudrappa et al., 2016; Giralol et al., 2021).

Bacterial vaccines

Bacterial infections are widespread in all eukaryotes. Numerous association processes have been emerged as a result between the co-evolution of bacteria and their hosts (Finlay and McFadden, 2006; Giesker and Hensel, 2014). Vertebrates evolved natural and adaptive immune systems, while bacteria used virulence mechanisms to circumvent antimicrobial processes (Finlay and McFadden, 2006; Giesker and Hensel, 2014).

Despite the growing use of antibiotics to combat disease-causing bacteria in humans and animals, antibiotic resistance is on the surge. (Giesker and Hensel, 2014). Antimicrobial resistance (AMR) is recognized by the World Health Organization (WHO) as one of the top 10 risks to the human health (Poolman, 2020). In 2015, 63.5% of AMR infections in Europe appeared to be healthcare-related, with adults 65 and older being the second-most affected population following the children (Cassini et al., 2019; Poolman, 2020). AMR is predicted to cause 700,000 deaths per year worldwide. Bacterial vaccines have the power to minimize AMR on many fronts. Vaccines can halt population- and healthcare-associated infections with multidrug-resistant (MDR) microbes, minimize antimicrobial use and resistance, and avoid infection in all age groups, specifically older adults, who have appeared as the age group with the greatest unaddressed vaccine needs (Nichol, 2005; Poland et al., 2009; Kennedy and Read, 2017; Klugman and Black, 2018; Poolman, 2020). Vaccines clearly avoid MDR infections and minimize antimicrobial use, but their potential utility in the battle against AMR, as well as their involvement in an integrated AMR strategy that involves targeted antimicrobials and enhanced diagnostics has yet to be realized (Kyaw et al., 2006; Bloom et al., 2018; Klugman and Black, 2018; Poolman, 2020).

Types of bacterial vaccines

Bacterial vaccines are divided into various categories.

- Toxoid:** Toxoids are toxins that have been chemically inactivated by bacteria such as *Clostridium tetani* (*C. tetani*) or *Corynebacterium diphtheria* (*C. diphtheria*). They are the exotoxins produced by these bacteria which trigger the disease, not the bacteria themselves. As a result, vaccination of toxoids induces the formation of antibodies towards the toxins, which neutralize the appropriate toxin and shield the body against a variety of serious diseases (Giesker and Hensel, 2014). *Bacillus anthracis* (*B. anthracis*) secretes two exotoxins: the edema factor (EF) and the lethal factor (LF). Both toxins share a defensive antigen (PA), which is required for binding and internalization of EF and LF within the host cell cytoplasm (Giesker and Hensel, 2014; Poolman, 2020). Immunity is induced by PA-based vaccines, which shield the cells against LF and EF attack. Six administrations with annual boosters are required for the immunization against these toxins (Reuveny et al., 2001; Giesker and Hensel, 2014).
- Subunit vaccines/polysaccharide vaccines:** Subunit vaccines, unlike toxoid vaccines, contain only a single pathogenic antigen. A subunit's immune response is weaker than that of a whole cell, but there is no chance of hyper-reaction or invasion when no microorganism is administered. When a purified protein, or even a single epitope of a protein, is administered, the immune

reaction is mediated through proteolytic digestion of the ingrained protein, preceded by antigen presentation on major histocompatibility complex (MHC) II. Since the following reaction is based on T cells, the proteins are referred to as T-dependent antigens. A T-independent immune response can also occur where the antigen is not a protein but rather is organized in a repetitive fashion or consisting of repetitive structures such as polysaccharides. The examples of polysaccharide vaccines are the vaccine against *Salmonella typhi* (*S. typhi*), (consisting of TY2 strain derived Vi capsular polysaccharide) and *Haemophilus influenzae* type b (Hib). However, since the T-independent immune response exists only in children aged 16–18 months, vaccination with the polysaccharide vaccine was ineffective (Giesker and Hensel, 2014).

- (c) Conjugate vaccines: Conjugate vaccines were produced by adding a protein to the capsular polysaccharide to improve the immune response and solve the issue of a delayed T-independent immune response. Three vaccines are used to defend against Hib, each with a different antigen, conjugation, and polysaccharide chain length and structure (Giesker and Hensel, 2014). These formulations, such as *Haemophilus* conjugate (HbOC) vaccine, polyribosyl phosphate-T (PRP-T) and polyribosyl phosphate outer membrane protein (PRP-OMP), are used effectively for disease prevention (Griffiths et al., 2012; Giesker and Hensel, 2014). Besides that, the ability to create synthetic vaccines that contain a PRP-tetanus toxin conjugate allows for large-scale vaccine development (Verez-Bencomo et al., 2004; Giesker and Hensel, 2014). In order to protect against *streptococcus pneumonia* (*S. pneumonia*), a polysaccharide conjugated to the diphtheria toxoid is administered, resulting in an immune reaction in both children and adolescents (Dagan et al., 2002; Verez-Bencomo et al., 2004; Giesker and Hensel, 2014). The major drawback of this conjugated vaccine over the subunit vaccine is that immunity is only achieved against seven serotypes, while the subunit vaccine targets 23 serotypes (Pittet and Posfay-Barbe, 2012; Wolfe, 2012; Giesker and Hensel, 2014). The meningococcal vaccine, which covers the serogroups A, C, W-135, and Y of 13 clinically important serotypes of *Neisseria meningitidis* (*N. meningitidis*), is another illustration of a conjugate vaccine (Rosenstein et al., 2001; Tunkel et al., 2004; Giesker and Hensel, 2014). Polysaccharides are attached to a diphtheria-toxoid polysaccharide-protein complex with this vaccine (Giesker and Hensel, 2014).
- (d) Inactive vaccines: Inactivated vaccines include bacterial cells that have been destroyed. The bacterium that causes a disease is inactivated using a chemical, heat, or radiation therapy. The cholera vaccine comprising of dead *Vibrio cholera* (*V. cholera*), had been used a lot longer but it only provide inadequate immunity for a brief time period after vaccination. The new vaccine is based on dead, inactive *V. cholera* with a recombinant B-subunit of this toxin. Following oral administration, this vaccine activates the immune system to develop antibodies against bacterial antigens, preventing intestinal invasion, as well as antibodies that neutralize the cholera toxin and hence preventing the toxin-diarrhea (Sinclair et al., 2011; Giesker and Hensel, 2014).
- (e) Live attenuated vaccine: Attenuated, living bacteria make up live vaccines. Attenuation can be accomplished by causing random or targeted mutations in virulence-related genes. Alternatively, to avoid the occurrence of the disease usually caused by the bacteria, less pathogenic strains or serotypes similar to the disease-causing agent may be used. Living bacteria cause a powerful immune response that lasts for a long time. The possibility of the attenuated bacteria reverting to a disease-causing agent is a limitation of this form of vaccine (Giesker and Hensel, 2014). Since the strains used retain latent virulence, their use poses hazards to vaccine recipients who have underlying immune suppressive deficiencies such as other diseases, inheritable immune abnormalities, or immunosuppressive medical care (Detmer and Glenting, 2006; Giesker and Hensel, 2014). The Ty21a typhoid vaccine having many mutations, including one in the Vi polysaccharide gene used by the subunit vaccine, is an example of an attenuated vaccine (Giesker and Hensel, 2014). The mutation in the *galE* gene causes the strain to be auxotrophic for galactose, thus prohibits the organism from surviving/growing outside of the laboratory (Detmer and Glenting, 2006; Giesker and Hensel, 2014). The vaccine against *Mycobacterium tuberculosis* (*M. tuberculosis*), BCG (Bacillus Calmette-Guérin) was developed from the Calmette-Guérin strain of *Mycobacterium bovis* (*M. bovis*) (Giesker and Hensel, 2014).
- (f) Recombinant vaccines: Recombinant vaccines are novel strategies of vaccination that use live attenuated bacteria as vectors of recombinant genes (Giesker and Hensel, 2014; Bloom et al., 2018). The primary reasons for recombinant protein-based vaccine production are the development of vaccines that are less reactive, more efficient, stronger, and better characterized, as well as vaccines that offer wider defense against various serotypes/serogroups of a bacterium (Unnikrishnan et al., 2012). When administered with adjuvants or represented by plasmids or harmless bacterial/viral vectors, recombinant vaccines depend on the ability of one or more defined antigens to trigger immunity against the pathogen (Nascimento and Leite, 2012).

Bacterial vaccine adjuvants and their mechanisms of action

Adjuvants are used to improve the vaccine-mediated immune response, which is particularly important when using subunit vaccines, which result in poor immunity when administered alone. The proper antigen-adjuvant balance is critical, since an adjuvant can be effective for one antigen but ineffective for another. Furthermore, the manner in which the vaccine is delivered has a significant impact on the adjuvant selection (Giesker and Hensel, 2014).

Aluminum salts (also known as alum) have been widely used in human vaccines for over a century. This type of adjuvant consists of aluminum hydroxide, aluminum phosphate and aluminum hydroxyl phosphate. Alum formulations are particulate in nature, on which vaccine antigens are adsorbed, though the properties of the various alum salts vary. This adsorption may result in improved antigen stability in vitro, leading to the initial presumption that alum provides a depot in situ, allowing for gradual antigen release over time and sustained immune system exposure (Ulmer, 2013).

Despite the fact that millions of people have been treated with alum-containing vaccines, the mechanism by which the alum boosts the immunity is still unknown. According to one hypothesis, alum causes necrosis accompanied by the release of uric acid. Uric acid is believed to activate dendritic cells (DC) and, as a result, the immune system (Kool et al., 2008; Giesker and Hensel, 2014). In addition to the approved adjuvants, there are a range of experimental models that stimulate the immune response in various ways. The adjuvants can provide a depot of antigen molecules that are released over time to mediate extended immunity. Adjuvants can also amplify local cytokines, thus activating specialized T cells (Giesker and Hensel, 2014). Besides that, adjuvants may help to stabilize epitopes or mediate antigen presentation via MHC I or II (Edelman, 2002; Giesker and Hensel, 2014). Mutant strains of the cholera toxin (CT) and an *Escherichia coli* (*E. coli*) heat-labile enterotoxin (LT) have been developed as effective adjuvants in mouse models, and nonliving antigen vaccines using mutant LT are now being used in clinical studies. Another experimental method is skin immunization, which has also been evaluated with the mixture of CT and tetanus toxoid, resulting in systemic immunity. An innovative diarrhea vaccine containing LT and an *E. coli* pilus protein has also been proved to regulate systemic immunity in humans studied under clinical experiments (Edelman, 2002; Giesker and Hensel, 2014).

Determinants of vaccine design

Immune evasion mechanisms used by bacteria

Bacteria employ a wide range of physical, biochemical, and immunological pathways to colonize and invade the human host while circumventing or neutralizing immune efforts to kill them (Urwin et al., 2004; Nizet, 2007; Silva Miranda et al., 2012; Poolman, 2020). Three important strategies adapted by bacteria are (1) antigenic variations/heterogeneity, typically in surface polysaccharides and/or surface proteins, so that type-specific immunity does not preclude concurrent infections with other variants of the same bacterium; examples include *S. pneumoniae*, *N. meningitidis*, *E. coli*, *H. influenza*, *Klebsiella pneumoniae* (*K. pneumoniae*), group A streptococcus. (2) Immune system modulation, whereby bacteria avoid destruction by interrupting/inactivating host defense strategies, examples include *Staphylococcus aureus* (*S. aureus*), *Bordetella pertussis* (*B. pertussis*), and group A streptococcus. (3) or lying in immune-inaccessible structures/locations. Examples include *M. tuberculosis*, *E. coli*, *S. aureus* and *Chlamydia trachomatis* (*C. trachomatis*) (Poolman, 2020).

These mechanisms have an effect on vaccine formulation, theoretically necessitating the use of various antigens/serotypes to optimize protection, or the inclusion of immune-boosting ingredients such as adjuvants.

Different sites of infection

The presence of protective antibodies in serum will help prevent diseases like meningitis and bacteremia/septicemia. The defensive amount of antibody has been determined for many invasive diseases. Hib, meningococcal, and pneumococcal conjugate vaccines that use T-cell aid to improve B-cell activities against capsular polysaccharides, as well as increase antibody synthesis and B memory cells, are very successful in inducing antibody responses to vaccine-specific serotypes/serogroups and show very high effectiveness (at least 75%) in reducing invasive disease (Lucero et al., 2009; Thumburu et al., 2015; Poolman, 2020). In stark comparison, the effectiveness of these same vaccines against mucosal diseases (otitis media and pneumonia) is just marginal. The effectiveness of pneumococcal conjugate vaccines (PCVs) against pneumonia in infants and adults aged 65 and over, as well as efficacy in avoiding otitis media, is up to 50% lower than that of bacteremia (Bonten et al., 2015; Poolman, 2020). The explanation for the suboptimal efficacy lies in the fact that antibodies caused by parenteral vaccination must travel via mucosal surfaces such as the middle ear, bladder epithelium, nasopharynx, and cervix by passive transudation (Wagner et al., 1987; Kaur et al., 2012; Scherpenisse et al., 2013; Poolman, 2020). The phagocytic opsonization necessitates the physical repositioning of neutrophils on the mucosal surfaces. Although the majority of infectious diseases enter the human body through mucosal surfaces, vaccinations that cause long-lasting defensive immune function at the mucosal surface have proven difficult to develop. Induction of bystander CD4 T-cell immunity and Trm swooping to the mucosa, in conjunction with attracting phagocytic cells, may hold the answer to this problem (Poolman, 2020).

Th1/Th17 induction and its function in mucosal infection control mechanism

If pathogenic bacteria penetrate the mucosa, CD4+Th1/Th17 T-cells are also needed to facilitate the role of opsonic antibodies by recruiting and activating the neutrophils and macrophages in order to clear extracellular pathogens. As a result, vaccines causing this form of reaction are needed (DeLyria et al., 2009; Poolman, 2020). However, Th1/Th17 responses alone are insufficient to deter mucosal infections. Antibodies are still the primary agents of bacterial killing and removal owing to their ease of mucosal penetration (Warfel et al., 2014; Brown et al., 2015; Middleton et al., 2017; Poolman, 2020).

The mucosal invasion of bacterial or parasitic agent activates the TLR, which in turn induces the release of specific cytokines produced by antigen presenting cells (APCs). These cytokines causes the activation of Th1/Th17 immune response. Interferon-gamma (IFN- γ) and interleukin (IL)-12, in particular, are important players in the differentiation of naive CD4 +T-cells into Th1 cells. In addition, the APCs induced interleukins such as IL-6 and IL-12, and growth factor β causes the naive CD4+T- cells to differentiate in to Th17 (Guglani and Khader, 2010; Poolman, 2020). IL-23 stabilizes and ROR γ t (transcription factor) regulates the differentiation process of Th17 (Korn et al., 2009; Poolman, 2020). The immune response associated with Th1 results in the production of tumor necrosis factor alpha (TNF- α), IL-2 and IFN- γ . When the intracellular Mtb, *S. enterica typhi* type pathogens enter in the body, these IFN- γ play an important role in destroying the pathogens by recruiting and differentiating the macrophages and dendritic cells of the body (Bao et al., 2000; Poolman, 2020). IL-17 primarily activates innate mucosal defenses,

especially neutrophil activation. Recent data indicates that this cytokine plays a role in activating the B-cell reaction by preferentially expressing the CXCL13 (a B-cell chemo-attractant) on Th17 cells (Takagi et al., 2008; Reinhardt et al., 2009; Poolman, 2020).

The Trm cells, which are formed in part from Th17 effector cells, serve as the first line of defense at mucosal sites of body such as the skin, lungs, vagina and urinary tract. Since, the trm cells are believed to kill antimicrobial resistant strains of *K. pneumoniae*, a subset of its lung resident performs this function by only producing INF- γ (Vesely et al., 2019; Poolman, 2020). The Whole-cell pertussis (wP) vaccination system, which have a longer period of defense than acellular pertussis (aP) vaccines and cause Th1/Th17-biased responses in infants as opposed to Th2-directed responses by aP, provide evidence that Th1/Th17 responses caused by vaccination can be effective (da Silva Antunes et al., 2018; Poolman, 2020). Adult BCG revaccination in India has also been shown to improve antimycobacterial induced Th1/Th17 reactions (Rakshit et al., 2019; Poolman, 2020). A south African study also evidenced that by the revaccination through BCG, the release of IFN- γ restricted the seroconversion of infection (Nemes et al., 2018; Poolman, 2020).

Immunological mechanisms and vaccines

The introduction of vaccination process was a breakthrough in the battle between bacteria and humans. Despite the fact that increased hygiene and antibiotics could have helped more people, vaccines are the most cost-effective and life-saving modalities in the history. Despite their effectiveness, one of the key tenets of vaccinology is that the large percentage of vaccines has been developed objectively, with a little knowledge of the immunological processes by which they cause defensive immunity. Despite decades of commitment, the inability to produce vaccinations against global pandemics such as HIV infection has highlighted the need to consider the immunological processes by which vaccines impart immune responses (Pulendran and Ahmed, 2011). The immune system has developed qualitatively distinct forms of responses to defend against different pathogens, it is now evident (Pulendran and Ahmed, 2011).

The immune system's action can be divided into two categories: primary and secondary immune responses. The primary immune response depicts the immune system's first encounter with an infectious agent, while the secondary immune response refers to all subsequent encounters with the same pathogen. In contrast to the primary immune response, the secondary immune response is quicker and better amid the production of memory cells, resulting in more successful pathogen removal. Vaccines imitate viruses, eliciting a primary immune response that is followed by a secondary immune response as the body is exposed to the true infectious agent (Giesker and Hensel, 2014). The immune response and the development of memory cells, both of which are essential for immunization, are complicated processes that will be discussed in the next section.

The MHC takes up, processes, and presents antigens that are found in the body. Both MHC I and MHC II have different functions. MHC I is located on most cells and presents endogenous peptides to cytotoxic T-lymphocytes (CTL), including self, tumor, and virus antigens. MHC I action is less relevant in bacterial vaccines since the administered antigens are normally exogenous. MHC II, unlike MHC I, can bind exogenous peptides; however, these complexes are only found on antigen-presenting cells (APC). MHC II is responsible for activating T-helper (TH) cells, which aid in the synchronization of the subsequent immune response. Innate immune cells, CTL, and phagocytes can all be activated by TH1 cells, resulting in a cell-mediated immune response that is directed against intracellular pathogens. The typhoid vaccine developed by using an attenuated *S. Typhi* strain Ty21a, which is already invasive, is an example of this mechanism during vaccination. TH2 cells stimulate B cells to produce antibodies against extracellular pathogens and poisons, triggering a humoral immune response. This immune reaction is also caused by toxoids, as well as inactivated or conjugated vaccines. The secretion of chemotactic molecules by TH17 cells attracts granulocytes to the infection site. Antibodies, also known as immunoglobulins (Ig), are present on the surface of B cells. IgM antibodies make up the bulk of antibodies on mature B cells, with just a few IgD antibodies present. Pentamers form when IgM is secreted, resulting in complexes of 10 epitopes. While each epitope's propensity for binding a ligand is poor, the abundance of epitopes compensates for this. The role of IgD in the body is still a mystery. B cells mature in the lymphatic tissues of the body's periphery. Unlike T cells, which can only detect antigens bound to the MHC, B cells can detect polysaccharides, glycoproteins, lipids, nucleic acids, or proteins that are attached to surfaces, linked to other chemical compositions, or secreted (Giesker and Hensel, 2014).

When antigens with repeated sequences, such as polysaccharides, cross-link the B-cell receptors, B cells can be activated without the presence of T cells. The B cells mature into IgM-secreting plasma cells after that, but so far no memory B cells could form. Chemical impulses from the bone marrow cause certain plasma cells to live for long periods of time, thus mediating memory. Vaccines such as the Hib subunit vaccine are using mechanism for immunization, but this vaccine is ineffective in children under the age of two because their immune systems are immature and do not react to vaccines of this type. T-dependent activation of B cells is needed for antigens with no repeated sequences. B cells proliferate and transform into plasma cells, which secrete antibodies, after being activated by TH2 cells. When the TH2 cell detects the antigen, but not exactly the same epitope as the B cell, the B cell is activated. B cells can switch their immunoglobulin class while the primary response is sophisticated. This is known as immunoglobulin class switching. Different Igs are formed depending on the form of TH cells that cause the isotope shift. The development of IgA and IgE is mediated by the secretion of cytokines by TH1 cells, which modulates the transition of the heavy chain of IgM to IgG. Most memory cells contain IgG antibodies, but B cells that express IgA and IgE antibodies also play a role in the secondary immune reaction. There are two types of memory T cells: effector memory T cells (TEM) and core memory T cells (TCM). TEM can be found in both blood and tissue. The secondary immune response can function quicker than the primary immune response because they are directly at the sites where new infections begin and the TEM start secreting cytokines. The greater immune response against

secondary infection is due to TCM. To diagnose new infections, the cells can be present in the blood and peripheral lymphatic tissue. Antigens allow TCM to proliferate and differentiate more quickly than naive T cells. TCM become TEM and are directed to infected tissues for TH1 or TH2 cell assistance after increasing cytokine output (Giesker and Hensel, 2014).

A subset of TCM stimulates memory B cells in body. DCs play a crucial function in immune responses. They are the strongest APCs, with the rare ability to display antigens in several ways. In order to activate CTL, antigens are produced from endosomes into the cytoplasm, segmented, and tied to MHC I molecules. The typical presentation of exogenous antigens by MHC II complexes is addressed by this procedure (Kim and Liao, 2010; Giesker and Hensel, 2014).

The limitations of existing bacterial vaccines

Bacteria developed various adaptive immune mechanisms during the co-evolution of the human immune system and pathogens. The immune system recognizes pathogens' surfaces as the first pattern it sees (Finlay and McFadden, 2006; Giesker and Hensel, 2014).

Antibodies are prevented from binding to surface molecules and being detected by immune receptors by capsules, which are made up of polysaccharide complexes that surround the bacteria. As opposed to non-encapsulated bacteria, encapsulation causes many differences in the immune system: the host's immune response is decreased, accompanied by a reduction in phagocytosis. *Porphyromonas gingivalis*, a bacterium implicated in periodontal disease, has a sevenfold greater phagocytosis of non-encapsulated bacteria in vitro than bacteria encased in a polysaccharide capsule. The longevity of encapsulated *P. gingivalis* is greater due to a lower phagocytosis rate, leading to higher virulence of the encapsulated bacteria relative to non-encapsulated *P. gingivalis* (Singh et al., 2011; Giesker and Hensel, 2014). Vaccines against antigens of the bacteria's surface are ineffective for bacteria with capsules since the immune system is unable to recognize the surface textures of encapsulated bacteria.

Due to capsular antigens, various serotypes must be taken into account while developing vaccines. Different serotypes can be included in polyvalent vaccinations, although not all serotypes can be addressed by polyvalent vaccinations for many pathogens (Ovodov, 2006; Giesker and Hensel, 2014).

The lipopolysaccharide (LPS) plays a crucial role in Gram-negative bacterial detection. LPS activates innate immune system receptors including the Toll-like receptor (TLR) 4, which has conserved components such as the lipid A core (Liechti and Goldberg, 2012; Giesker and Hensel, 2014).

The O antigen, on the other hand, is found on the outside of the LPS and is very variable. This is an example of antigenic diversity in bacterial pattern, which results in the formation of various serotypes or serovars. Bacteria employ antigenic changes to facilitate reinfection or to prolong an infection. Different alleles or mutable sequences in the molecules cause the variances (Finlay and McFadden, 2006; Giesker and Hensel, 2014).

More than 2500 serotypes of *Salmonella enterica* (*S. enterica*) are capable of colonizing humans and causing a variety of illnesses (Andrews-Polymenis et al., 2010; Giesker and Hensel, 2014). When the immune response is reliant on serotype variation, infection with one serotype does not induce immunization against other serotypes (Finlay and McFadden, 2006; Giesker and Hensel, 2014). Following immunization against a serotype-specific pattern, memory cells specific to that pattern form followed by immunity to that serotype alone. To address this issue, polyvalent vaccinations based on several strains have been developed (Pittet and Posfay-Barbe, 2012; Giesker and Hensel, 2014).

Another example of immune evasion is *M. tuberculosis* secreting ESAT-6, a key T-cell antigen into host cells, which prevents the TH1 cell response (Dwivedi et al., 2012; Giesker and Hensel, 2014). As a result, even if vaccination was administered, the immune system will be unable to effectively remove the illness. Other examples include *Yersinia pestis* (*Y. pestis*) induced paralyzes of phagocytic functions and other methods of interfering with the immune system, such as blocking cytokines both of which result in a reduced immunological response with no influence on vaccination (Finlay and McFadden, 2006; Giesker and Hensel, 2014).

The use of an efficient vaccination technique puts bacterial pathogens under selection pressure. As a result, pathogenic strains with variants or mutations in genes that encode antigenic structures might emerge. These modifications will impact the pathogen's antigenic characteristics and may allow it to evade immune responses generated by vaccination. The rise of non-typeable *H. influenza* isolates as a result of the widely used Hib capsular vaccination is a good example of such serotype drift. Immune defenses focused against capsule antigens have little effect on non-typeable *H. influenzae* strains, which have lost capsule expression (Giesker and Hensel, 2014).

Vaccination schedules and travelers vaccines

Vaccination is a very efficient way to avoid various infectious illnesses. Vaccines are typically considered to be quite safe, as major side effects are unusual. Immunization programs prevent the majority of the world's youngsters against a variety of deadly illnesses that used to kill millions of people every year. Vaccination provides travelers with the opportunity to avoid several infectious illnesses that they may encounter while traveling. However, adequate vaccinations for some of the most life-threatening illnesses have yet to be discovered; as a result, other measures, such as avoiding mosquito bites, hand washing, as well as general precautions should be observed. Each vaccine plan must be customized by a physician based on the traveler's past immunizations, health condition, risk factors, the countries of visit, the nature and duration of trip, types of activities, and the amount of time available prior to departure. The immunological response of the vaccinated individual varies depending on the type of vaccine, the number of doses given, and whether or not the individual has formerly been vaccinated for the same illness. At least 2 weeks prior to travel, all vaccines should be done (Table 1).

Table 1 Summary of vaccination for travels.

<i>Categories</i>	<i>Vaccines used against</i>	<i>The justification for vaccination</i>
(1) Regular vaccinations to evaluate before traveling	Pneumococcal Tuberculosis Influenza Diphtheria Pertussis Tetanus	Most national childhood vaccination programs include these vaccinations. A pre-travel consultation, on the other hand, is an excellent chance for health care practitioners to examine the immunization status of babies, children, adolescents, and adults and confirm that they have received immunizations according to their own country's schedule
(2) Vaccines advised for particular travel destinations	Cholera Meningococcal Typhoid fever	These vaccinations are suggested for protection against illnesses that are endemic to the origin or destination country. They're designed to keep travelers safe and prevent disease from spreading inside and between nations
(3) Vaccines required by some states	Vaccine against meningococcal disease. On the WHO's Weekly Epidemiological Record web page, there are specific updates for pilgrims heading to Saudi Arabia	For passengers intending to enter or depart a country, several governments demand proof of immunization. See the country list on WHO's International Travel and Health (ITH) web page for more information

Table is adopted and modified from https://www.who.int/ith/CHAPTER_6_For_Publication.pdf.

Vaccine administration, like any other injection, requires a high level of injection protection. For each injection, a sterile needle and syringe must always be used, and thus should be disposed of properly. Where appropriate, the WHO suggests using only single-use ("auto-disable") syringes and, ideally, devices with sharps injury prevention capabilities. Syringes must not be recapped (to prevent needle-stick injuries) and should be discarded in a rational way for the receiver, the administrator and the community.

The use of vaccine combinations or co-administration with other vaccines

Several combination vaccines that defend against many diseases are now available and additional combinations are expected to become possible in the future. Combination vaccinations help travelers save time and money by reducing the amount of doses they need. Combination vaccines are generally almost as safe and reliable as single-disease vaccines.

Generally, inactivated vaccines do not interact with other vaccines. Many injections in a single visit, on the other hand, should be provided at various locations (different limbs) for each injection, or injection sites should be separated by at least 2.5 cm (1 in.). When administered at various anatomical locations, most live vaccines may be delivered at the same time. If injectable live virus vaccines are not given on the same day, they should be given at least 4 weeks apart. Live oral Ty21a typhoid vaccines, on the other hand, can be given at any time pre- or post-administration of injectable live vaccines (Table 2; CDC, n.d.).

Recent developments in bacterial vaccines

Adjuvants and other delivery modes for improving mucosal immune responses

Adjuvants are immune-stimulatory chemicals that help the immune system work well. AS01 (TLR4 agonist with saponin QS21) and CpG (TLR9 agonist) are the most latest adjuvants to be licensed in human vaccines (Cunningham et al., 2016; Poolman, 2020). AS01 is found not only in the extremely successful RZV vaccination, but also in the experimental TB vaccine M72/AS01E, which exhibited statistically significant effectiveness in preventing pulmonary TB in adults infected with MTB suggesting that AS01 might be a good adjuvant for other mucosal infections. CpG has been licensed as part of a hepatitis B vaccine (Poolman, 2020).

The programming of receptors (tissue-specific adhesion and chemo-attractant receptors) that govern T- and B-cell migration to mucosal regions is determined by the place where dendritic cells encounter antigen. It's been challenging to obtain high quantities of T-cells at mucous membranes following systemic immunization so far (Lai et al., 2015; Poolman, 2020). Alternative vaccination methods (oral, sublingual, inhaled, intranasal, transdermal, intra-vaginal) paired with adjuvants may promote T-cell localization to specific mucosal regions, such as Trm cells (Li et al., 2020; Poolman, 2020).

Vaccine against extraintestinal pathogenic *Escherichia coli* (ExPEC) and *Streptococcus pneumoniae*

The most prevalent cause of UTI is ExPEC. According to preliminary findings from Phase 1–2 research, a systemic vaccination to prevent UTI may be possible. In one trial, women with a history of recurrent UTI (Huttner et al., 2017) were given a prototype 4-valent ExPEC bioconjugate vaccination. Another study looked at a vaccination that included FimH from type 1 fimbriae as well as a novel adjuvant (Poolman, 2020). ExPEC conjugate vaccines offer a strong possibility of preventing invasive ExPEC illness (mostly bacteremia and urosepsis), but mucosal immunity would most likely need to be improved. Modification of the formulation to stimulate a Th1/Th17 response, as with previous combination vaccines, may assist in achieving clinically significant effectiveness against UTI. A similar strategy might be used to boost PCV effectiveness against non-bacteraemic pneumonia (Ramos-Sevillano et al., 2019), albeit achieving a well-balanced response is getting increasingly difficult. After human challenge, a proposed pneumococcal vaccine including three proteins with Th1/Th17-inducing potential (SP0148, SP1912, SP2108), but with

Table 2 Vaccines for both regular and targeted use.*Cholera prophylaxis**Brief introduction about disease*

Causative organism	<i>Vibrio cholera</i> Serotype: O1 and O139
Mode of transmission	Infection happens when food or water is polluted, either directly or indirectly, by the feces or vomitus of infected people
Nature and severity of disease	Acute enteric disorder of differing degrees of seriousness. The majority of viruses have no symptoms (i.e., they do not cause illness). Acute watery diarrhea develops without any symptoms in minor conditions. In acute conditions, there is an abrupt onset of watery diarrhea, nausea, and vomiting, as well as accelerated dehydration. Dehydration, which leads to circulatory failure, can cause death in serious untreated cases within a few hours
Global prevalence	Cholera is most common in low-income countries and regions where healthcare has failed and there is a shortage of sanitation and safe drinking water
Risks associated with traveling	Except in places where cholera epidemics exist, the risk to most travelers is very low if basic measures such as hygiene are taken. Humanitarian aid personnel in flood zones and refugee camps, on the other hand, could be at risk
General precautionary measures	Consumption of highly infected food, beverages, and water should be discouraged, along with other diarrheal diseases. In the event of acute diarrhea, oral rehydration salts should be taken to prevent dehydration and electrolyte depletion. No country needs cholera vaccine as a condition of entrance

Vaccination

Vaccine type	(1) Killed vaccine of O1 whole cell containing β subunit (2) killed vaccine of O1 and O139 Route of administration: Oral
Vaccination schedules	(a) Two doses for people under the age of six, and three doses for children between the ages of two and five. 7 days and 6 weeks can be the time interval between doses. Booster doses are prescribed after 2 years for children under the age of 6 and after 6 months for children over the age of 25. Primary vaccine should be repeated if the prescribed times between primary doses or even between previous primary dose and a booster dose are not met (b) There are two doses. Individuals under the age of 1 year are separated by 14 days. Within 2 years, all age ranges can get a booster dose.
Contraindicated	In persons experiencing hypersensitivity to prior dose
Special consideration for	High risk travelers (e.g., emergency/relief staff)
Precautionary measures related to vaccine	There are none
Use in pregnancy or lactating mothers	Oral inactivated vaccine can be administered if indicated

Diphtheria prophylaxis

Diphtheria vaccine is regularly given to children in most countries. Vaccines should be available to travelers who have postponed their vaccinations, according to national guidelines

Brief introduction about disease

Causative organism	The toxigenic <i>Corynebacterium diphtheriae</i> and seldomly the toxigenic <i>Corynebacterium ulcerans</i> often found in tropical climates
Mode of transmission	<i>C. diphtheriae</i> , which lives in the respiratory tract, is spread from human to human through droplets and near physical contact; <i>C. ulcerans</i> and <i>C. pseudotuberculosis</i> can also be carried through zoonotic transmission.
Nature and severity of disease	Clinical signs and symptoms are generally moderate, but powerful bacterial toxins may sometimes inflict obstructive membranes in the upper respiratory tract or cause disruption of the myocardium and other tissues. <i>C. ulcerans</i> and <i>C. tuberculosis</i> are less probable to provoke systemic symptoms.
Global prevalence	In countries where diphtheria-vaccines are widely used, it is very rare. In crowded areas with inadequate vaccine programmes and poor sanitation, the prevalence of the disease increases.
Risks associated with traveling	The risk of infection raises in populations with low vaccination rates against diphtheria, tetanus, and pertussis (DTP).
Vaccination schedules	National guidelines suggest using properly developed combination DTP vaccinations or booster tetanus and diphtheria (Td) vaccines for primary or booster vaccination. Individuals under the age of seven can obtain diphtheria toxoid-free varieties.
Use in pregnancy or lactating mothers	Can be administered if indicated

Tetanus prophylaxis

Tetanus vaccine is regularly given to children in most countries. According to guidelines, unvaccinated travelers should be given the vaccination

Brief introduction about disease

Causative organism	The toxigenic bacteria, <i>Clostridium tetani</i>
Mode of transmission	<i>C. tetani</i> spores can contaminate necrotic, anaerobic tissue and turn into toxigenic, vegetative bacteria. Tetanus is not contagious
Nature and severity of disease	Local muscular spasms or systemic muscle spasms and rigidity can be caused by potential bacterial neurotoxins derived from vegetative <i>C. tetani</i> . Tetanus, particularly generalized tetanus, is sometimes lethal if left untreated
Global prevalence	<i>C. tetani</i> spores can be found all over the world, mainly in soil

Table 2 (Continued)*Tetanus prophylaxis*

Risks associated with traveling	Activities that potentially contribute to dirty or infected injuries are related to the risk. This chance isn't really elevated while traveling
Vaccination schedules	According to national guidelines, travelers should be treated with the combination diphtheria–tetanus or DTP vaccinations. Tetanus-containing formulations with low diphtheria toxoid content should be provided to children under the age of seven
Adverse reactions to vaccines	Anaphylaxis and brachial neuritis
Use in pregnancy or lactating mothers	Can be administered if indicated.

Pertussis prophylaxis

Pertussis vaccine is regularly provided to children in most countries. Vaccines can be recommended to unvaccinated travelers in accordance with national guidelines

Brief introduction about disease

Causative organism	<i>Bordetella pertussis</i>
Mode of transmission	<i>B. pertussis</i> is spread by droplets from one individual to another
Nature and severity of disease	Only ciliated cells of the respiratory mucosa are colonized by <i>Bordetella</i> bacteria, resulting in an acute respiratory infection (also known as whooping cough) with intense, spasmodic coughing bouts. Pertussis can be atypical and often life-threatening in early childhood
Global prevalence	With advancing age, disease symptoms become less dramatic, even in adults The prevalence of pertussis is dependent on DTP immunization rates; the disease is more prevalent in countries with poor coverage and is less common in countries with high DTP immunization
Risks associated with traveling	Unvaccinated children entering countries with poor DTP vaccine coverage are at the greatest risk
Vaccination schedules	Acellular or whole-cell (WC) pertussis vaccinations can be used in established combination with vaccines against diphtheria (D) and tetanus (T) for primary and booster vaccination. The schedule should adhere to national guidelines. Individuals under the age of seven can obtain diphtheria toxoid-free varieties
Use in pregnancy or lactating mothers	Only acellular vaccine can be administered if indicated

Haemophilus influenzae type b prophylaxis

In certain countries, children are regularly immunized against *Haemophilus influenzae* type b (Hib). According to guidelines, unvaccinated travelers under the age of five should be given vaccine

Brief introduction about disease

Causative organism	<i>H. influenzae</i> type b (Hib)
Mode of transmission	Respiratory Droplets
Nature and severity of disease	Hib is a leading cause of pneumonia, meningitis, septicemia, epiglottitis infection, and other potentially fatal infections in children aged 3 months to 5 years old
Global prevalence	In countries with poor Hib vaccine coverage, it is common
Risks associated with traveling	In an area with poor Hib vaccine coverage, the risk is likely to rise
Vaccination schedules	All Hib vaccines licensed for marketing are conjugated. Their carrier protein, chemical conjugation process, polysaccharide sizing, and adjuvant differ. Hib vaccine comes in a number of forms, including liquid Hib conjugate vaccine (monovalent), liquid Hib conjugate vaccine mixed with DTP and/or hepatitis B vaccine, Hib conjugate in conjunction with meningococcal antigens, lyophilized Hib conjugate with saline diluent (monovalent), lyophilized Hib conjugate for use with liquid DTP or DTP in combination with other antigens, such as hepatitis B vaccine and inactivated polio vaccine Three primary doses without the need for a booster; two primary doses with a booster; and three primary doses plus a booster, with the first dose as soon as possible after 6 weeks of age. For healthy children over the age of five, the Hib vaccine is not needed

Tuberculosis prophylaxis

The tuberculosis (TB) vaccine for small children is not tailored to the needs of travelers. A single dose of bacillus Calmette–Guérin (BCG) vaccine should be given annually to all stable neonates at birth in countries or settings with a high prevalence of tuberculosis (TB) and/or leprosy. Unvaccinated young kids who are exposed to a high prevalence of tuberculosis should be given vaccines in accordance with national guidelines

Brief introduction about disease

Causative organism	<i>Mycobacterium tuberculosis</i>
Mode of transmission	by inhaling airborne droplets contaminated with <i>M. tuberculosis</i>

(Continued)

Table 2 (Continued)*Tuberculosis prophylaxis*

Nature and severity of disease	Many <i>M. tuberculosis</i> exposures manifest in latent infection, which only rarely progresses to active disease. TB can affect any organ, but active pulmonary disease of mycobacterial transmission is the most common manifestation in terms of public health. Tuberculous meningitis or disease propagation may occur in children. <i>M. tuberculosis</i> multidrug resistance (MDR) is an increasingly growing problem
Global prevalence	Poor people all over the world, but particularly in low-income countries. In HIV-positive people, tuberculosis is very common
Risks associated with traveling	The probability of travel-associated tuberculosis is determined by a number of factors, including the prevalence of tuberculosis in the country visited, the length of travel, the extent of contact with local population, and, most importantly, the traveler's age. Until vaccination of unvaccinated visitors null by the tuberculin skin test and the interferon release assay from regions that are not endemic for TB, an individual risk estimate dependent on the period of travel and the TB occurrence in traveling country, should be regarded. Vaccination is recommended for young unvaccinated children traveling to countries with a high risk of tuberculosis, particularly those who are likely to travel often during their childhood
Precautionary measures	Travelers should prevent frequent, direct contact with people who have pulmonary tuberculosis, if at all necessary. For health personnel and humanitarian aid staff, a tuberculin skin test before and during a high-risk mission abroad might be recommended. Travelers who have been exposed to individuals with bacteriologically proven tuberculosis for an extended period of time should be able to get preventive care
Vaccination schedules	Live attenuated mycobacterial strains derived from the first attenuated BCG are used in BCG vaccines. Apart from its reported effectiveness against tuberculous meningitis and disseminated disease in children, BCG vaccination has little benefit for most travelers
Adverse reactions to vaccines	Suppurative lymphadenitis (mostly in immunodeficient persons), osteitis (very rare with current vaccines) and disseminated BCG infection
Use in pregnant or lactating mothers	No

*Typhoid fever prophylaxis**Brief introduction about disease*

Causative organism	<i>Salmonella Typhi</i> causes typhoid fever, a serious, possibly fatal, acute, generalized infection. <i>S. paratyphi</i> A and B (and, less frequently, <i>S. paratyphi</i> C) cause paratyphoid fever, which is clinically similar to typhoid fever, particularly in Asia. Only humans are infected by <i>S. Typhi</i> and <i>S. Paratyphi</i> . Typhoid fever and paratyphoid fever are both referred to as "enteric fever"
Mode of transmission	The bacillus that causes typhoid is spread by infected food or drink. Direct fecal oral transmission can happen on rare instances. Shellfish from wastewater-polluted areas are a major cause of contamination; raw fruit and vegetables fertilized with human excreta, as well as infected milk and milk products, are other sources of infection. Flies can spread infectious agents to humans by transmitting them to food. When a large majority of individuals are using the same source of drinking water, pollution of water bodies can lead to typhoid fever epidemics
Nature and severity of disease	Pink stains, which disappear with pressure, occur on the trunk skin in up to 20% of light-skinned patients. Untreated patients may develop gastrointestinal and cerebral problems in the third week, which can be fatal in up to 10% of untreated cases. Kids under the age of four have the highest case-fatality rates. Since the bacteria remain in the biliary tract after symptoms have subsided, about 25% of sick individuals become chronically infected
Global prevalence	Typhoid fever is most likely to spread in countries or regions with poor sanitation, health, and water supplies
Risks associated with traveling	Typhoid fever is a problem for all visitors to endemic areas, but the risk is relatively low in tourist and business centers with high levels of lodging, sanitation, and food hygiene. Parts of Sub-Saharan Africa, as well as South and Southeast Asia, have strong endemicity. Travelers in other parts of the world are normally only at risk when they are subject to poor sanitation. For those who have been vaccinated should take precautions to prevent drinking highly infected food and drink, since the vaccination does not provide 100% immunity. In typhoid-endemic countries, the occurrence and spread of antimicrobial resistance among <i>S. Typhi</i> isolates is on the rise
Vaccination schedules	Travelers to places where the risk of typhoid fever is high, particularly those staying in endemic areas for more than 1 month and/or in regions where antimicrobial resistance strains of <i>S. Typhi</i> are common, may be provided vaccination. A booster dose of the Ty21a vaccine is prescribed after 1–7 years, based on national guidelines, for previously vaccinated visitors from non-endemic to endemic areas, and then after 3 years for the ViPS vaccine
Type of vaccine	There are three varieties of typhoid vaccines on the market, currently: (1) The Vi polysaccharide antigen is bound to a carrier protein in the latest generation typhoid conjugate vaccine (TCV). Currently, the only TCVs that have been approved are those that are bound to the tetanus toxoid protein (numerous different TCVs with various carrier proteins are in clinical trials and will be approved in the coming years). TCV is currently approved as a single intramuscular dosage in babies and children starting at the age of 6 months, as well as adults over the age of 45. (2) The oral Ty21a vaccine is rooted on a <i>Salmonella Typhi</i> strain that has been live attenuated. It comes in enteric-coated capsules and is intended for children under the age of six. Primary vaccine comprises of three or four capsules (one capsule on alternate days) depending on national guidelines. After 17 years, it is advised that you get vaccinated again. Ty21a has mainly been used to shield travelers.

Table 2 (Continued)*Typhoid fever prophylaxis*

Contraindicated in	(3) The Vi capsular polysaccharide (ViPS) vaccine is an injectable unconjugated Vi capsular polysaccharide (ViPS) vaccine that is administered intramuscularly or subcutaneously in a single dose to people under the age of two. Revaccination is advised every 3 years to ensure safety. In certain countries, a combination typhoid–hepatitis A vaccine is also accessible
Adverse reactions to vaccines	In individuals allergic to vaccine's ingredients Over 30 years of use, both the Ty21a and unconjugated ViPS vaccines have shown to be effective and well tolerated. Until now, the newer-generation TCV has a favorable safety profile (similar to ViPS), with no significant side effects recorded
Precautionary measures for vaccination	Antibiotics should not be provided to people who are taking Ty21a. Ty21a can be taken with chloroquine, but not after 8–24 h after mefloquine has been administered.
Use in pregnancy or lactating mothers	There is no definitive proof that proguanil and Ty21a should be administered together Should be avoided as safety data is not determined

Pneumococcal disease prophylaxis

Travelers are not at an elevated risk of contracting pneumococcal disease, but access to quality health services may be restricted when on the trip

Brief introduction about disease

Causative organism	Various serogroups of <i>Streptococcus pneumoniae</i>
Mode of transmission	<i>S. pneumoniae</i> -infected respiratory droplets
Nature and severity of disease	Invasive and non-invasive disease can also be caused by pneumococcus. Upper respiratory tract infections (URTI's) and non-bacteraemic pneumonia are the most prevalent non-invasive pneumococcal infections. The most frequent symptoms of invasive pneumococcal infection include pneumonia with empyema and/or bacteremia, febrile bacteremia, and meningitis. Antibiotic resistance in these bacteria is becoming a growing concern. Non-bacteraemic pneumonia and invasive pneumococcal diseases both have a high mortality rate, particularly in small children, the elderly and immunocompromised
Global prevalence	Found around the world
Risks associated with traveling	The pneumococcal conjugate vaccine (PCV) is universally approved for children. Children under the age of two, as well as children and adults deemed to be at high risk of severe illness, should be recommended to get vaccinated against infectious pneumococcal disease when traveling to areas with insufficient access to current health care services
Vaccination schedules	(1) Pneumococcal conjugate vaccines with 10 (PCV10) or 13 (PCV13) serotypes. From the age of 6 weeks, these PCVs can be given in a three-dose regimen of two or three main doses with or without a booster. PCV10 and PCV13 are vaccines towards invasive illness, pneumonia, and acute otitis media affected by the respective <i>S. pneumoniae</i> vaccine serotypes. PCV13 is also approved for use by adults (2) A pneumococcal polysaccharide vaccine that includes 23 serotypes of pneumococcal bacteria (PPV23). This vaccine is only for children under the age of two. Although the potency and efficacy of PPV23 in children and adults are unknown, it is considered healthy
Adverse reactions to vaccines	Anaphylaxis (very rare)
Use in pregnancy or lactating mothers	

*Meningococcal disease prophylaxis**Brief introduction about disease*

Causative organism	Serogroups A, B, C, W, X, and Y of the <i>Neisseria meningitidis</i> bacteria are the most common causative organisms
Mode of transmission	Direct person-to-person touch and respiratory droplets from infected or asymptomatic meningococcal carriers are the two most common ways for meningococcal infection to spread. Humans are the sole source of contamination
Nature and severity of disease	Children and teenagers are the primary victims of endemic illness, with babies aged 3–12 months having the highest attack rates. Meningococcal meningitis causes a severe headache, fever, nausea, fatigue, photophobia, sore neck, and other neurological symptoms to appear suddenly. Permanent neurological consequences are normal, and the disease kills 5–10% of people. Hypovolemic shock, hemorrhagic skin rash, and a high fatality risk describe meningococcal septicaemia
Global prevalence	There are sporadic cases all around the world. The majority of cases occur in temperate areas during the winter months. Regionalized outbreaks have been reported in crowded, confined areas (e.g., dormitories and military barracks). Wide outbreaks of meningitis can occur in the meningitis belt of Sub-Saharan Africa during the dry weather (November to June). Outbreaks of “serogroup A” have practically vanished in all countries that have adopted mass vaccination programmes for the category A conjugate vaccine. Latest meningococcal spreads caused by serogroups Y (United States), W (Saudi Arabia and sub-Saharan Africa), C, and X (sub-Saharan Africa) indicate that these serogroups are becoming more significant
Risks associated with traveling	Travelers have a low risk of contracting meningococcal disease. Travelers to high-income countries are at risk of contracting intermittent cases of A, B, or C. Meningococcal C disease outbreaks are common in schools, hospitals, military barracks, and other areas where large groups of teenagers and young adults reside. Travelers to the Sub-Saharan meningitis belt may be vulnerable to outbreaks, the most frequent of which are serogroups A, C, and W, which have much higher occurrence rates during the dry season. Long-term visitors living in close proximity to the local people, as well as pilgrims performing the hajj or umrah in Mecca, are particularly vulnerable

(Continued)

Table 2 (Continued)*Meningococcal disease prophylaxis*

<i>Vaccination</i>	
Vaccine types	Bivalent (A and C), trivalent (A, C, and W), and tetravalent (A, C, W, and Y) polysaccharide vaccines that cover two to four meningococcal serotypes are accessible. Polysaccharide vaccines are being phased out in favor of: (1) single-valent (A or C or C/Hib combination), two-valent (A and C, or C and Y/Hib combination), and four-valent (A, C, W, and Y) conjugate vaccinations are available. (2) Whilst recombinant protein-based vaccines towards serogroup B infections have become available around the world, only a few countries prescribe them. There is no universal guideline for travelers to be vaccinated against serogroup B
Vaccination schedules	Polysaccharide vaccines are given in a single (usually subcutaneous) dose to children under the age of two. After 35 years, a booster will be needed. In the case of conjugate vaccines, a principle sequence of one to three intramuscular doses is recommended, followed by boosters. The vaccination schedule is determined by the injection, as well as the vaccinee's age and immunological condition. While several countries already prescribe a primary sequence of two or three intramuscular doses for recombinant-protein-based vaccinations, WHO has yet to devise guidelines for national programmes
Contraindicated in	Individuals allergic to vaccine components
Adverse reactions to vaccine	With the exception of anaphylaxis, all meningococcal vaccines have a very good safety record
Use in pregnancy or lactating mothers	Can be administered if indicated

*Anthrax prophylaxis**Brief introduction about disease*

Causative organism	Spores of the bacterium, <i>Bacillus anthracis</i>
Mode of transmission	The spores are very resistant to inactivation and can live for years in the soil, infecting livestock who swallow the spores. Animals such as goats, sheep, and cattle are susceptible to infection. Anthrax spores may infect humans through three different routes: cutaneous (through the skin), gastrointestinal (through ingestion), and pulmonary (through inhalation)
Nature and severity of disease	Signs and symptoms of disease range from bumps or blisters (cutaneous anthrax), nausea, vomiting, swelling, stomach pain (gastrointestinal anthrax), sore throat, difficulty in breathing, shortness of breath (inhalational anthrax), fever and chills. If left untreated, anthrax can spread to other parts and cause serious sickness, including brain infections and even death
Consideration for	High risk individuals such as laboratory workers, military personnel, emergency/relief staff and individuals handling infected animals
Vaccine type	Immunization with anthrax vaccine is the only established and efficacious pre-exposure prophylaxis against anthrax. An attenuated strain of <i>B. anthracis</i> was used to create the vaccine. The vaccine is made from this strain's cell-free culture filtrate and is adsorbed onto an aluminum salt in its final product
Vaccination schedule	Three doses of vaccine followed by booster doses in individuals. Unvaccinated persons of all ages who have been exposed to anthrax should get the anthrax vaccination. These individuals should receive three doses of anthrax vaccination, as well as the antibiotics prescribed
Adverse reactions to vaccine	Headache, fatigue, muscle aches, tenderness etc.
Use in pregnancy or lactating mothers	For pregnant women who have been exposed to anthrax, anthrax vaccine may be suggested. Pregnant women, on the other hand, are not advised to obtain the vaccination if the risk of anthrax exposure is minimal

Table is adopted and modified by taking the information from <https://www.cdc.gov/vaccines/hcp/vis/vis-statements/anthrax.html>.

Th2-inducing aluminum hydroxide as adjuvant, lacked effectiveness for pneumococcal colonization (Poolman, 2020). A protein pneumococcal proposed vaccine including aluminum phosphate similarly failed to prevent colonization (Odutola et al., 2017), whilst a protein vaccine with a powerful Th1 adjuvant rescued non-human primates from pneumonia (Denoël et al., 2011; Poolman, 2020).

Vaccine against *Staphylococcus aureus*

The development of a *S. aureus* vaccine has proven to be significantly more challenging than expected. *S. aureus* thrives at immune evasion, and a string of vaccination failures based on capsular polysaccharides and surface proteins shows that an effective vaccine will almost certainly require to neutralize numerous major immune evasion mechanisms (Redi et al., 2018; Poolman, 2020). It uses a variety of immune evasion strategies to thwart immunological responses (B- and T-cell superantigens), limit leukocyte recruitment, induce neutrophil lysis, disrupt the complement activation, induce oxidative burst killing resistance, offer innate AM resistance, attach and destroy immunoglobulins, and construct a protective fibrin capsule around the bacteria (Guerra et al., 2017; Poolman, 2020). Although it is unknown which and how many of these processes must be suppressed to give disease protection, the traditional technique of employing surface antigens (capsular conjugates or proteins) has so far been ineffective. Nabi (CP5 and CP8 conjugates), Merck (IsdB), and Pfizer (CP5 and CP8 conjugates, ClfA, and MntC) all had failed vaccination

candidates with similar characteristics: a small number of surface antigens, no immune-evasion-related options, no adjuvants, inability to produce a CD4⁺ Th1/Th17 immunological response, and a non-representative animal studies (mice) (Fowler et al., 2013; Fattom et al., 2015; Redi et al., 2018; Poolman, 2020). Based on these difficulties, a successful technique will require a multicomponent strategy, which might include immune-escape related candidate antigens, a more accurate animal model, and the inclusion of a Th1/Th17 adjuvant to boost the immune response (Brown et al., 2015; Poolman, 2020). Th1 (IFN- γ) and Th17 (IL-17A) cells are required for macrophage and neutrophil proliferation and recruitment (Bröker et al., 2016; Poolman, 2020). Staphylococcal infections are predisposed by genetic abnormalities in phagocyte function, Th17, and IL-17RA, corroborating the pathways mentioned above (Lévy et al., 2016; Poolman, 2020).

Vaccine against tuberculosis

M. tuberculosis is an intracellular pathogen with a lipoidal surface shape that makes immunological assault even more difficult. After infection, granulomas are formed by the aggregation of macrophages and monocytes, as well as the presence of chemokines that stimulate cell adhesion and T-cell recruitment, frequently leading to a protracted latent period of infection (Silva Miranda et al., 2012; Poolman, 2020). The Bacille Calmette-Guerin (BCG) vaccination has been used in children ever since 1960s and has proven to be effective in avoiding disseminated TB. BCG appears to accelerate the spread of MTb from alveolar macrophages to tissue- or lung-recruited macrophages and neutrophils through antigen-specific CD4 T-cells (Delahaye et al., 2019; Poolman, 2020). Through as yet unknown methods, this transfer to phagocytes, as well as their activation and differentiation, is considered to improve the ability to limit bacterial proliferation (Delahaye et al., 2019; Poolman, 2020). BCG boosts the potential of innate effector cellular response to non-specific stimuli by inducing acquired immunity (Joosten et al., 2018; Covián et al., 2019; Poolman, 2020). Reactivation of disease may avoid this stage, contributing to BCG's decreased efficiency in avoiding lung TB reactivation in infected adults, which is the most prevalent cause of TB-related mortality (Trunz et al., 2006; Poolman, 2020).

The prophylactic adaptive response is assumed to be mediated mostly by CD4⁺ Th1 cells, with contributions from Th17 and CD8⁺ T-cells, although there is still no convincing explanation for how bacterial killing is accomplished (Tubo and Jenkins, 2014; Andersen and Scriba, 2019; Poolman, 2020). BCG revaccination increased Th1/Th17 CD4⁺ T-cell responses, including poly-functional T-cells, in IGRA+ (IFN- γ release assay related to presence of Mycobacteria) individuals, according to recent studies from India (Rakshit et al., 2019; Poolman, 2020).

When given as a booster, BCG prevented persistent seroconversion (as measured by the IFN-release test) in South African adolescents (Nemes et al., 2018; Poolman, 2020). Newly designed live-attenuated mycobacterial vaccines (MTBVAC; VPM1002) are being tested as possible BCG replacements or modifications (World Health Organization, 2019; Poolman, 2020). Although the immunology of CD4⁺ reactions in TB has garnered a lot of study, the function of bacterial virulence mechanisms has gotten less attention (Andersen and Scriba, 2019; Poolman, 2020). Inadequate understanding of MTB secretory systems and bacterial defenses against reactive oxygen and nitrogen molecules, as well as poorly defined processes of bacterial virulence and immune protection, are significant barriers in the development of a better TB vaccine, making target antigen selection difficult. Killed whole-cell (WC), live attenuated, adjuvant subunit, and viral-vectored designs are among the 11 TB vaccine candidates now in clinical development (recently reviewed) (Andersen and Scriba, 2019; Poolman, 2020). Several vaccinations are being developed as adjuncts to TB treatment (MIP, Vaccae, H56: IC131, RUTI™, and ID93/GLA-SE). Given the relative simplicity of identifying clinical endpoints, the invention of therapeutic vaccines for use in integrated methods with antibiotic therapy might move quickly, and might be a “fast win” in terms of enhancing clinical outcomes in the treatment of MDR tuberculosis. Four adjuvanted subunit vaccines are now being tested in clinical trials. These molecules consist of proteins whose functionality and relevance to virulence aren't always understood. All these vaccines and two viral-vectored vaccines (AERAS-402 and MVA85A) elicited functional Th1 CD4⁺ T-cell responses, with no substantial CD8⁺ T-cells or IL-17 production; the main difference was that recipients of M72/AS01_E (GSK), a recombinant fusion protein with AS01, had greater cytokine responses (Rodo et al., 2019; Poolman, 2020). The viral-vectored candidate vaccines AERAS-402 and MVA85A were used in a prime-boost study, which indicated that the booster dosage increased CD8⁺ T-cell responses, however these appeared short-lived. In infected people in South Africa, Kenya, and Zambia (Sheehan et al., 2015; Van Der Meeren et al., 2018), immunization with M72/AS01_E offered 54% protection (90% CI 13.9–75.4) against active pulmonary TB illness after 2 years of follow-up. After 3 years, vaccine effectiveness was 49.7% (90% confidence interval 12.1–71.2) (Tait et al., 2019; Poolman, 2020).

H56:IC31, a fusion protein and IC31 adjuvant, is being aimed at preventing TB illness in infected people of all ages as a supplement to antimicrobial therapy. This vaccine option produces antigen-specific Th1 immune responses in infected and non-infected individuals (Suliman et al., 2019), and its effectiveness as an additional therapy is being studied in two Phase 2 trials. Subunit vaccines now contain a small number of antigens whose individual protective properties remain unclear (Schrager et al., 2018; Poolman, 2020). To increase the confidence of antigen selection, a revitalized systemic full-genome based antigen development is required. Extended subunit compositions are now being studied as DNA or viral (cytomegalovirus)-vectored vaccines (Griffiths et al., 2016; Hansen et al., 2018; Poolman, 2020).

Conclusion and future perspective

The benefits of combining various vaccines or developing more polyvalent vaccines include reduced frequency of shots, lower risks of infection following vaccination and less cost of vaccination administration. Despite the promising results of laboratory

investigations using live attenuated vaccines, human immunization with live recombinant vaccines is still a work in progress. The latent pathogenicity of such carriers might result in infections among immuno-compromised patients and/or it can produce different results in practical use as compared to experimental studies.

Currently, majority of the vaccines are administered through intramuscular or intravenous injections to induce systemic immunity. This can lead to increased risk of infections at injection site as well as an uprising need of trained health care personals. The mucosal vaccination can serve as an alternate to injections. The possibility of degradation, resulting in a lower dose of vaccine, must be addressed for oral immunization.

Vaccine against cancer has also been experimented in mouse models by using inactivated whole cancerous cells. However these vaccines have not been tested on human tumor cells. Furthermore, the use of inactivated cancer cells may result in disease reactivation. Effective human anticancer vaccines can be developed by identifying the tumor specific antigens. Additional obstacles in the development of cancer vaccines must be considered: When cancer vaccines are tested, patients are frequently given immunosuppressive conventional medication, which prevents the immune system from functioning correctly. Similarly, the human immune system's effectiveness deteriorates with age. Vaccines cannot provide the same level of immunity in older cancer patients as they can in younger individuals.

This is important to foster vaccine firms to create vaccinations that are beneficial for the public but may not be economically feasible. Given the critical role of vaccinations in lowering resistance, failing to address these concerns might become a global problem.

Glossary

Adjuvant An exogenous immunostimulatory agent added to vaccines to enhance immunogenicity. Adjuvants improve immune response and stimulate humoral and/or cellular immunity to improve the protective capacity of vaccines.

Attenuation The process of modification of the biology of a strain of virus by serial passage in tissue culture. Attenuation in cell culture has been a hallmark of vaccine discovery and has provided the basis by which many vaccines currently in clinical practice were developed.

Contact immunity A phenomenon whereby individuals acquire vaccine-induced immunity by virtue of close contact with immunized individuals who transmit the live, attenuated strain of vaccine to the naïve individual. Contact immunity can, in effect, immunize unvaccinated individuals secondarily through contact with vaccinated individuals. This is known to be an attribute of oral polio vaccination.

DNA vaccine Vaccine strategy in which a recombinant DNA molecule encoding a viral gene product (protein) of interest is administered to an individual, toward the goal of inducing a protective immune response.

Herd immunity Vaccine-induced protection of a population based on the acquired immunity of a large percentage of individuals residing in that community. When vaccine rates are high, the likelihood of herd immunity is high, and disease rates are low because of the lack of susceptible individuals.

Intussusception A form of intestinal blockage, usually observed in infants, where a portion of bowel collapses into the lumen of the adjacent bowel, creating a 'telescope'-like effect. This phenomenon was observed with first-generation rotavirus vaccines; though never causally proven, it did lead to the withdrawal of one rotavirus vaccine from the market.

mRNA vaccine A novel vaccine strategy, first evaluated in human subjects in the context of the COVID-19 pandemic, in which a messenger RNA (mRNA) encoding a viral gene product (protein) of interest is administered to an individual, toward the goal of inducing a protective immune response.

Subunit vaccine A vaccine designed and manufactured to induce antibody responses against one or more particular proteins or constituents of a pathogenic virus. Subunit vaccines typically utilize cloning technologies to express immunological targets of interest in a variety of expression systems.

VAPP Vaccine-associated paralytic poliomyelitis. This occurs when the specific attenuating mutations in the oral polio vaccine are lost due to reversion to wild-type sequence. The resulting revertant virus is capable of neurovirulence leading to paralytic polio.

Vector vaccine A vaccine approach in which an immunogen of interest (such as SARS-CoV-2 Spike protein) is inserted into another, attenuated viral vector. Immunization of the individual with the vector in turn induces an immune response to the gene product of the pathogen, resulting in protective immunity against that virus.

Introduction

Credit for the first use of vaccines in humans has historically gone to Edward Jenner, who is considered the pioneer of the smallpox vaccine (Eyler, 2003). The work of Jenner took place in the late eighteenth century, but in fact, the history of smallpox vaccination dates back to much earlier times in human history, when the process of “variolaion” (inoculating a susceptible individual with the dried scab or secretions from another person with the smallpox) was practiced as long ago as the tenth century in China (Gross and Sepkowitz, 1998). Smallpox vaccination represents the prototype of a “live, attenuated” viral vaccine, discussed in the following section (see also Table 1). The second category of vaccines in clinical use is the so-called “subunit” vaccine, typically based on the immunization of a susceptible individual with one or more proteins important in immunity against the pathogen of concern (Table 2). Usually these protein-based vaccines are administered with an immunostimulatory adjuvant (defined below). Broadly speaking, nucleic acid-based vaccines (DNA and mRNA) can be considered as “subunit” vaccines, since they are typically predicated on the administration of a nucleic acid sequence encoding a single (or limited number of) viral gene product(s). Finally, there is a sub-category of subunit vaccines in clinical use referred to as “vectored” vaccines. These vaccines use an innocuous and attenuated agent, usually a replication-incompetent virus, to express a foreign gene from a heterologous pathogen. Expression of the gene product following immunization induces protective immunity to the pathogenic virus. Most of the important vaccines used in clinical practice today fall into one of these categories. In this article, clinically important viral vaccines are listed in the accompanying tables, and some of the most important viral vaccines used in medical practice today are reviewed and compared in the text. The impetus behind the rationale for a vaccine’s design is provided, as well as the proposed mechanism(s) of protection. The need for new, novel immunizations against viral pathogens for which no vaccines are currently available is briefly discussed.

Table 1 Live, attenuated viral vaccines in clinical practice.

<i>Vaccine</i>	<i>Indication</i>	<i>Route of administration</i>	<i>Comments</i>
Smallpox (vaccinia)	Smallpox prevention.	Intradermal.	• Not current recommended for routine use. • Potential future role in bioterrorism disease control?
Oral polio vaccine (OPV)	Polio prevention.	Oral; three-dose series.	• Serotypes 1–3. • Contact immunity. • Intestinal/mucosal immunity. • Risk of VAPP.
Live, attenuated influenza vaccine (LAIV)	Influenza prevention.	Intranasal.	• No longer used in developed world. • Attenuated by cell culture passage at 25 °C. • Induces mucosal (IgA) responses in addition to IgG response.
Mumps, measles, and rubella vaccine (MMR)	Prevention of mumps, measles and rubella infections.	Subcutaneous (preferred) or intramuscular.	• Approved for ages 2–49 years • Three vaccines are combined for convenience and ease of dosing. • Vaccine initiated at 15 months. • Second dose required in later childhood.
Rotavirus vaccine	Prevention of rotavirus infection (epidemic gastroenteritis).	Oral; two- or three-dose series.	• Two vaccines currently licensed in U.S. are either human rotavirus-derived attenuated vaccine or bovine/human reassortants. • Vaccination begins in the first 1–2 months of life. • Intestinal/mucosal immunity. • Serum IgG response.
Live, attenuated varicella-zoster virus (VZV) vaccine for chicken pox (varicella); live, attenuated vaccine for Herpes Zoster (shingles)	Prevention of chicken pox; prevention of shingles (Herpes Zoster).	Subcutaneous or intramuscular.	• Protects against chicken pox when administered in two-dose series to VZV seronegatives. • Protects against reactivation (shingles or herpes zoster) when given to adults with past history of chicken pox. • Live attenuated Zoster vaccine no longer available in the U.S. but still in use in other countries.
CYD-TDV	Prevention of Dengue fever.	Subcutaneous administration; three-dose series.	• Live attenuated tetravalent chimeric vaccine. • Three-doses at every 2 month intervals. • CYD-TDV is partially effective in preventing infection, but vaccination may lead to severe disease in those who have not been previously infected and then acquire natural infection.

Table 2 Killed/inactivated/subunit/vectored viral vaccines used in clinical practice.

<i>Vaccine</i>	<i>Indication</i>	<i>Route of administration</i>	<i>Comments</i>
Hepatitis A	Prevention of hepatitis A infection.	Intramuscular; two-dose series.	- Formalin-inactivated virus proteins from cell culture. - Adjuvanted with aluminum hydroxide. - Induces protective IgG response. - Recommendation for universal childhood immunization.
Hepatitis B	Prevention of hepatitis B infection.	Intramuscular; three-dose series. A combined hepatitis A/hepatitis B vaccine, 'Twinrix,' is also licensed in the U.S. (see text for details).	- Based on single viral protein, hepatitis B surface antigen (HBsAg). - Expressed using cloned, recombinant expression in <i>Saccharomyces cerevisiae</i>. - Adjuvanted with aluminum hydroxide. - Induces protective IgG response to HBsAg. - Recent new two-dose recombinant HB surface antigen vaccine approved, similar to previous vaccines, includes a novel CpG 1018 adjuvant, a 22-mer phosphorothioate-linked oligodeoxynucleotide. - Cancer prevention vaccine. - Universal recommendation for childhood immunization.
Inactivated/subunit influenza vaccines	Influenza prevention.	Intramuscular.	- Formalin-inactivated ('split virion') vaccines. - Both trivalent and tetra-valent formulations available. - Mechanism of action: induction of anti-HA (hemagglutinin) and influenza virus-neutralizing IgG responses. - Vaccine virus cultivated in embryonated eggs; other cell culture systems are available including eucaryotic cell culture and insect cell culture for egg-allergic patients. - A high-dose vaccine with 4 times the total influenza protein in licensed in the US for individuals >65 years. - An adjuvanted flu vaccine with MF59C.1 adjuvant is licensed for individuals >65 years. - Universal immunization against influenza recommended for all individuals >6 month of age in US.
HPV vaccine	Prevention of HPV infection.	Intramuscular; CDC recommends that 11- to 12-year-olds receive two doses of HPV vaccine 6 to 12 months apart; only two doses are recommended if vaccination started at age 9 and through age 14, but teens and young adults who start the series later, at ages 15 through 26 years, need three doses of HPV vaccine.	- Bivalent (16, 18). Quadrivalent (6, 11, 16, 18) and nine-valent (9vHPV; types 6, 11, 16, 18, 31, 33, 45, 52, and 58) have been licensed by FDA. - Vaccine manufactured as recombinant protein in a yeast cell culture system (<i>Saccharomyces cerevisiae</i>). - Nine-valent formulation is the only HPV vaccine currently distributed in the U.S.
Japanese Encephalitis Virus Vaccine	Prevention of Japanese Encephalitis Virus infection.	Two-dose series, subcutaneous administration.	- Mosquito-borne <i>Flavivirus</i> infection. - Endemic in Western Pacific and Southeast Asian Regions. - Formalin-inactivated, multi-component viral vaccine currently is approved in the USA, but DNA vaccines and attenuated vaccines also in various stages of clinical development globally.
Herpes Zoster (Shingles) vaccine	Prevention of Herpes Zoster.	Intramuscular, two-dose series.	- Based on VZV glycoprotein E protein. - Adjuvanted with AS01B adjuvant. - Protects against reactivation (shingles or Herpes Zoster) when given to adults with past history of chicken pox.
SARS-CoV-2 (COVID 19) vaccines	Prevention of infection and/or reduction of disease, reduced risk of hospitalization and death due to COVID-19.	mRNA/lipid nanoparticle vaccines (BNT162b2 and mRNA-1273): intramuscular administration, 2 dose series plus a third (booster) dose. Adenovirus-vectored vaccine (Ad26.COV2-S COVID-19 vaccine): initial dose by intramuscular route followed by booster dose.	- BNT162b vaccine requires two doses given 21 days apart. - The mRNA1273 vaccine requires two shots spaced 28 days apart. - Recommendation for third (booster) dose for both mRNA vaccines 6 months following second dose. - Both mRNA vaccines encode for the SARS-CoV-2 (COVID) "Spike" glycoprotein (but expressed as RNA molecule). - Ad26.COV2-S COVID-19 vaccine administered at least 2 months following initial dose. - Ad26.COV2-S COVID-19 vaccine expresses Spike protein in the context of recombinant adenovirus vector (and hence has a replication incompetent virus vector backbone), and does not contain adjuvant.

Live, attenuated viral vaccines

Smallpox vaccine

As noted, the first known vaccine used in the history of humanity was a vaccine against smallpox (also known as variola). Edward Jenner received credit for developing the first smallpox vaccine. As history has it, Jenner observed that milkmaids exposed to cowpox appeared to be “resistant” to acquisition of smallpox. Jenner tested whether inoculation of subjects with material from cowpox lesions protected individuals against smallpox upon direct exposure. Indeed, the approach was successful, and the term “vaccination” (derived from the Latin word *vacca*, meaning “cow”) was used to describe the procedure. Although Jenner receives credit for developing the smallpox vaccine – and, indeed, creating the field of vaccinology – other contemporaries of Jenner had observed the protective effect against smallpox conferred by exposure to cowpox, most notably Dr. Benjamin Jesty (Eyler, 2003), in the years leading up to Jenner’s groundbreaking experiments.

Although initial approaches to smallpox vaccination utilized cowpox virus, the smallpox vaccine historically employed in clinical practice was based on vaccinia, another related poxvirus, but one that has minimal potential for virulence in healthy, immune-competent humans. Smallpox vaccine administration was unique compared to most other viral vaccines, insofar as it was administered by skin prick using a novel, two-pronged needle. Smallpox vaccine was extraordinarily successful globally and, indeed, smallpox is today the only disease in the history of humanity eradicated by immunization (Smith, 2013). Globally, the last known case of smallpox was reported in Somalia in 1977, and routine smallpox vaccination was discontinued in the United States in the early 1970s. After the terrorist attacks of September 11, 2001, smallpox immunization was reinitiated in some potentially high-risk populations, including health care providers and military personnel, in anticipation of the possible use (never realized) of weaponized smallpox virus by terrorists as a biological weapon (Arita, 2005). Since smallpox vaccine was discontinued, there has been an apparent emergence of the highly related monkeypox infection in humans, due to the loss of cross-protective immunity formerly conferred by smallpox immunization (Sklenovská and Van Ranst, 2018).

To this day, the principles of Jenner’s approach – based on the recognition of strong biological similarities of infectious syndromes across different species – are employed in the design and production of live, attenuated viral vaccines for human use. This is sometimes referred to as a “Jennerian” approach, and can include propagation of human pathogens on cells of heterologous species toward the goal of attenuation of the pathogens (varicella vaccine, measles vaccine), or actually using components of the related vertebrate virus (rotavirus vaccine) in creating the human vaccine. Individual examples are considered in further detail below.

Live, attenuated polio vaccine

Poliovirus is a member of the enterovirus family of human pathogens. Although most individuals with polio infection have a mild, self-limited illness, a small but substantial percentage will have polio infection spread to the brain and/or spinal cord, where it can lead to paralysis and potentially death. By the early 1950s in the United States, polio epidemics had become devastating. For example, between 1951 and 1954, there were over 10,000 cases of paralytic poliomyelitis reported every year to the Centers for Disease Control and Prevention (Nathanson and Kew, 2010).

Two polio vaccines emerged in clinical practice in the late 1950s/early 1960s (Melnick, 1996). The first vaccine, the so-called Salk vaccine, is a killed, whole-virion protein vaccine (reviewed below). The second licensed vaccine, the Sabin vaccine, is a live, attenuated vaccine. Both vaccines are still used today, although the Sabin vaccine is not currently used in the United States. The Sabin vaccine is made up of three different serotypes of poliovirus (types 1–3), all of which can cause paralytic polio. The vaccine was originally created by passage of polio in primary monkey and human diploid cell cultures, at subphysiological temperatures that allowed growth of virus, but facilitated the accumulation of attenuating mutations. Following tissue culture passage, mutations accumulate in the sequence of all three strains that lead to a loss of virulence and an inability of the viruses to produce paralysis. These mutations have been mapped in detail (Kew et al., 2005). One of the features of these attenuating mutations is a reduction in the ability of viral messenger RNA to be translated by the ribosome.

The oral polio vaccine (OPV) is administered in a four-dose series. The vaccine contains mixtures of all three attenuated polioviruses. The attenuated vaccine strains replicate very efficiently in the gastrointestinal tract, as does wild-type poliovirus, which probably contributes to an enhanced immune response compared to inactivated polio vaccine. This so-called intestinal immunity appears to include mucosal IgA responses that enhance the protective effect of the vaccine. Moreover, the vaccine virus is excreted in the stool of immunized patients. This excreted vaccine virus can, in turn, be ingested by a nonvaccinated individual, leading to secondary (contact) immunization, via the fecal–oral route of ingestion. Thus, this creates the potential for “contact immunity”, namely, the idea that others will be secondarily immunized by being in close contact with individuals who receive the vaccine. This phenomenon contributes to the preference for oral polio vaccination in regions where wild-type polio is still highly endemic. Unfortunately, polio vaccine virus also has the potential to revert back to wild-type sequence in the gastrointestinal tract in immunized patients, and can in fact revert to a fully neurovirulent genotype, particularly in children with immune deficiency. This exposure to revertant virus can lead to paralysis, and this “vaccine associated paralytic poliomyelitis” (VAPP) phenomenon was responsible for 8–10 cases of polio in the United States every year until OPV use was discontinued in the United States in the late 1990s. Wild-type poliovirus has been absent from the Western hemisphere since 1991, although occasionally neurovirulent revertant strains of polio are still observed (Alexander et al., 2009), presumably due to importation from countries still using

OPV. Some of these revertant strains are capable of circulating in vaccine-naïve populations and producing paralytic poliomyelitis (Gumede et al., 2013). For regions of the world where polio is still endemic and epidemic, however, OPV has been considered to be the preferred vaccine for population-based immunization. Considerable progress has been made toward global polio eradication (Modlin et al., 2021), facilitated by the global SARS-CoV-2 pandemic, since the recent global vaccination drive against COVID-19 has increased the public dialog about the great need for vaccines, including polio vaccine (Ali et al., 2021).

Influenza vaccine (live, attenuated)

Influenza is an RNA virus in the *Orthomyxoviridae* family. There are two major subtypes of influenza virus: influenza A and influenza B. Both are important human pathogens, although humans are not the natural host for influenza (wild aquatic birds are the natural host). Influenza has a segmented RNA genome and influenza A virus can undergo extensive recombination in nature, leading to the appearance of genetically variant strains not previously encountered in the human population. When this process – known as “antigenic shift” – occurs, an influenza pandemic can ensue, leading to extensive mortality. The influenza pandemic of 1918 resulted in an estimated 50,000,000–100,000,000 deaths globally (Morens and Fauci, 2007). Even in a “normal” influenza season, it is estimated that 40,000–50,000 deaths every year in the United States are attributable to influenza infection. Universal annual influenza administration is recommended for everyone over 6 months of age in the United States.

Live, attenuated influenza vaccines (LAIVs) have only recently become available for clinical use. These vaccines are prepared by passing clinical isolates of influenza in cell culture using subphysiological temperatures. This process of “cold adaptation” – used in the generation of other live, attenuated viral vaccines considered in this article – led to the development of the current LAIVs used in clinical practice (Jang and Seong, 2012). Since the process of cold adaptation in cell culture was undertaken at temperatures (25 °C) incompatible with replication of virus at core body temperature (37 °C), these vaccines are highly attenuated and extremely safe. The vaccine is administered in the form of a nasal drop or spray on an annual basis. The vaccine is trivalent, containing two strains of influenza A and a single strain of influenza B, or tetravalent, containing two strains of influenza A and two strains of influenza B, depending upon the manufacturer. The strains chosen to compose the vaccine each flu season depend upon what strains of influenza have recently circulated, or are predicted by public health officials, to be circulating in the upcoming influenza “season”. LAIV is not recommended for children under 2 years of age, or individuals over 50 years. The mechanism of protection is the induction of IgG antibody to influenza, in particular hemagglutination-inhibition antibody.

Measles vaccine

Measles is a highly contagious viral infection spread from person to person predominately by aerosol (droplet) route. It is a member of the *Paramyxoviridae* family of viruses. Measles infections used to be so ubiquitous in nature that it is assumed that all individuals born in the United States before 1957 are immune to the measles virus. Prior to the advent of vaccination, measles (also known as rubeola) caused considerable mortality globally, with over 2 million deaths annually in children (Cutts et al., 2013). Measles infection causes cough, coryza (runny nose), and conjunctivitis, as well as a classic morbilliform (“measles-like”) rash. In addition to the classic rash of rubeola, measles infection is responsible for severe, occasionally fatal pneumonia, tracheobronchitis, and encephalitis. Measles infection can also produce long-term complications, in particular subacute sclerosing panencephalitis, a chronic and uniformly fatal encephalitis caused by persistence of measles virus in the central nervous system. Measles infection strongly suppresses the host immune system and predisposes patients (particularly young children) to develop other serious infections, including tuberculosis. Remarkably, measles infection has been shown to “erase” immune memory, potentially resulting in the loss of protection conferred by other vaccines (Petrova et al., 2019). Measles is also an important cause of blindness in the developing world. Although considerable progress has been made in preventing measles-associated morbidity and mortality, over 100,000 measles deaths occurred in 2010, underscoring the need for continued vigilance in vaccination programs (Cutts et al., 2012).

Measles vaccine is a live, attenuated vaccine. Attenuation of this virus occurred following serial passage in a nonpermissive cell line, in the case of measles, cells of avian origin. There have been several measles virus variants used as vaccines in clinical practice since the advent of immunization programs in the early 1960s. The original vaccine strain was named the “Edmonston” strain, after the child from whom the wild-type virus was originally isolated (Hilleman, 1992). The process by which serial passage of the measles virus in cell culture produces attenuation remains unclear, although a recent study demonstrated varying amino acid substitutions in all of the viral proteins encoded by the measles genome in vaccine strains (Bankamp et al., 2011). Measles vaccine is administered by the subcutaneous route, typically at 15 months of age. This vaccine is usually combined with the mumps and rubella vaccines (hence, the MMR vaccine, for mumps–measles–rubella). A second dose of vaccine is recommended later in childhood. The vaccine appears to work by induction of antibody responses to measles envelope glycoproteins, particularly the hemagglutinin protein involved in binding of measles virus to its cellular receptor (Hashiguchi et al., 2011).

Mumps vaccine

Mumps is a paramyxovirus and, as such, highly genetically related to other common childhood infections such as measles, respiratory syncytial virus, and parainfluenza virus. Mumps infections can be associated with parotitis, orchitis (rarely causing infertility), aseptic meningitis, and sensorineural deafness.

Mumps vaccine is based upon attenuating serial passage of what was originally a clinical isolate of mumps virus, the “Jeryl Lynn” strain. This strain is actually a mixture of two distinct, closely related strains (Afzal et al., 1993). Other attenuated strains, including the Zagreb strain, have been used in the development of live attenuated mumps vaccine (Ivancic et al., 2005). The precise molecular basis of attenuation is not known. The vaccine is administered by subcutaneous or intramuscular route, typically in combination with measles and rubella vaccine (MMR vaccine). The protective mechanism appears to be via induction of antibody to mumps virus surface glycoproteins. Mumps outbreaks have occurred on a university campus in spite of the fact that 95% of the affected students had received two doses of the MMR vaccine. The susceptibility appeared to be related to a suboptimal mumps antibody titer (Cortese et al., 2011), suggesting that future modifications of mumps vaccine will be required.

Rubella vaccine

Rubella virus is an enveloped, single-stranded, positive-sense RNA virus belonging to the *Togaviridae* family. Although togaviruses are typically vector-borne infections, rubella is the notable exception, being transmitted instead by a respiratory droplet route. Humans are the only known natural host for rubella virus. Rubella infection, commonly known as the “German measles”, usually results in a mild illness with an accompanying exanthem in adults and children; however, rubella produces serious consequences in the pregnant patient, where fetal infection can lead to severe anomalies including microcephaly, sensorineural deafness, and cardiac defects (Freij et al., 1988). An ophthalmologist, Norman Gregg, offered the first description of congenital rubella syndrome (CRS) in 1941, while investigating an epidemic of neonatal cataracts (Gregg, 1947). Not until the global pandemic of 1964–65, however, were the multiple teratogenic manifestations of CRS fully appreciated and the permanent neurodevelopmental consequences for newborns completely recognized. The capacity to grow the virus in tissue culture led rapidly to the development of the vaccine and to a reduction in CRS in the United States and other developed countries.

Rubella vaccines are classic live attenuated viral vaccines, prepared through the process of long-term cell culture passage, which in turn leads to attenuating mutations in wild-type sequences. In clinical practice, most vaccines are derived from the Wistar RA 27/3 strain of virus. Although the strains used in vaccines have been sequenced, the molecular basis of attenuation is unclear (Kakizawa et al., 2001). The vaccine is administered by subcutaneous route or intramuscular route, typically in combination with measles and mumps vaccine (MMR vaccine). The protective mechanism appears to be via induction of antibody to rubella virus surface glycoproteins. Rubella has been eradicated from the Western Hemisphere (Plotkin, 2021), although routine MMR administration continues to be recommended to guard against any resurgence of disease. A combination vaccine containing both MMR and Varicella vaccine – ‘MMRV’ vaccine – has been licensed in the United States. Unless the parent expresses a preference for MMRV vaccine, the CDC recommends that MMR vaccine and varicella vaccine should be administered as separate injections for the first dose in children 12–47 months of age, with use of MMRV combination vaccine reserved for use as a “booster” dose in later childhood.

Rotavirus vaccine

Rotaviruses are members of the *Reoviridae* family. They are unique among pathogenic viruses by virtue of the fact that their genomes are double-stranded, segmented, RNA genomes. Rotavirus, prior to the advent of vaccination, was the most important cause of viral gastroenteritis, particularly in children (Vesikari, 2012). Rotavirus infection in young children can be responsible for severe diarrhea and attendant fluid and electrolyte abnormalities, and causes considerable mortality in the developing world, where supportive care resources are limited. It was estimated that, globally, rotavirus infection caused more than 450,000 deaths in children under 5 years of age in 2008 (Tate et al., 2012).

Rotaviruses are common in vertebrates, and such viruses (i.e., rhesus macaque rotavirus, bovine rotavirus) share many molecular and biological similarities with human rotavirus. These similarities have been exploited in vaccine design. The first human rotavirus vaccine (licensed in the late 1990s) was a so-called “rhesus reassortant” virus made up of four live viruses: a rhesus rotavirus (serotype G3) and three rhesus–human reassortant viruses (comprising both human and rhesus rotavirus components) that were specific for serotypes G1, G2, and G4. Thus, the vaccine was designed to protect against the four rotavirus serotypes that were responsible for most rotavirus disease in the United States at that time (Vesikari, 2012). This vaccine was successful in preventing rotavirus disease in children following a three-dose series, but was withdrawn from the market because of a possible association with a complication known as intussusception, a complication resulting in intestinal blockage (Peter and Myers, 2002). Subsequently, two new rotavirus vaccines were licensed in the United States and remain in widespread use. These newer vaccines do not appear to carry a risk of intussusception. The first is a live, attenuated human rotavirus vaccine derived from an infant with rotavirus gastroenteritis (G1 strain). This vaccine protects across most of the different serogroups of rotavirus in circulation, not just the G1 serotype. It is recommended for use in a two-dose schedule beginning at 6 weeks of age. The second is another human–animal (bovine) reassortant vaccine. This vaccine contains five live reassortant rotaviruses: four of these express the G1, G2, G3, or G4 VP7 protein from their respective parent human strain and an attachment protein from a bovine strain, and the fifth expresses an attachment protein from a human strain and a VP7 protein from a G6 bovine strain (Dennehy, 2008). This vaccine is recommended for use in a three-dose series, at 2-month intervals, beginning at 6–12 weeks of age. Both vaccines are highly effective in preventing rotavirus infection.

All licensed rotavirus vaccines are administered by the oral route, analogous to the use of the OPV. The correlate of protective immunity induced by vaccination appears to be IgG antibody. However, there is some evidence that an equally important correlate of protective immunity following vaccination may be the IgA response (Patel et al., 2013).

Varicella-zoster virus vaccine

Varicella-zoster virus (VZV) is the etiologic agent of chicken pox. Although most children with chicken pox have an uneventful recovery, prior to the advent of vaccination there were approximately 100 varicella deaths in otherwise immune-competent children in the United States every year, due to pneumonia, neurological complications such as encephalitis, or secondary infections caused by *Streptococcus pyogenes* (Nguyen et al., 2005). As a member of the *Herpesviridae* family of viruses, it is capable of establishing latent infection in the dorsal root ganglia, where it resides in quiescent form for years or even decades before reactivating. When VZV reactivates, it produces a rash on the skin surface corresponding to the region of the skin innervated by that particular ganglia; such a reactivation is known as Herpes Zoster or “shingles” (Schleiss, 2009). Herpes Zoster can lead to postherpetic neuralgia, which can cause debilitating pain for prolonged periods of time, particularly in elderly patients (Gershon and Gershon, 2013). Hence, there is a strong medical rationale for a VZV vaccine both to prevent chicken pox (vaccine given to VZV-naïve subjects) as well as prevent episodes of zoster (vaccine given to those with a history of chicken pox).

VZV vaccine was derived from a clinical isolate known as the “Oka” strain. This strain was originally obtained in the early 1970s from a young child with chicken pox (Takahashi et al., 1974), and was passaged in cell culture, including extensive passages in both guinea pig cell culture as well as human cells (Takahashi et al., 2008). Some of the cell culture passages were at a reduced temperature (34 °C). As is the case for so many other live, attenuated viral vaccines, the precise molecular basis for the attenuation of the virus was unknown at the time of the vaccine’s licensure, although recent studies have begun to shed light on the specific molecular mutations that arose during serial tissue culture passage that appear to have contributed to the reduction of virulence (Peters et al., 2012). The vaccine has been variably used in the United States in three formulations: a monovalent formulation (“Varivax”) for children and young adults; MMRV vaccine; and a monovalent formulation for adults over 60 years of age for prevention of herpes zoster (shingles). The vaccine is given subcutaneously. Two doses of vaccine are administered for prevention of chicken pox, while a single dose of vaccine had been recommended for older individuals receiving the vaccine to prevent shingles. Although the live, attenuated shingles vaccine is still available in some countries, it is no longer available in the United States, and has largely been supplanted by the adjuvanted, VZV glycoprotein E subunit vaccine, which has been shown to be highly effective at preventing shingles (Heineman et al., 2019).

Subunit viral vaccines

Hepatitis A vaccine

Hepatitis A is an RNA virus in the *Picornaviridae* family. It is readily transmissible by the fecal–oral route and is highly contagious. Food-borne outbreaks are common. Infection leads to liver inflammation (“hepatitis”), vomiting, diarrhea, and jaundice. Jaundice may be absent in young children with acute infection. Although most infections are self-resolving, infection can lead to fulminant hepatic failure in some cases (Brundage and Fitzpatrick, 2006). Subunit vaccines based on formalin-inactivated hepatitis A virus, cultivated in MRC-5 cells, are licensed and marketed by two manufacturers in the United States. Hepatitis A vaccine is also combined with hepatitis B in another vaccine licensed in the United States, a product known as “Twinrix”. Both are adjuvanted with aluminum hydroxide adjuvant. Two doses, given by intramuscular route and separated by at least 6 months, are recommended. The mechanism of protection is believed to be by induction of hepatitis A-specific IgG antibody response.

Hepatitis B vaccine

Hepatitis B virus is a double-stranded DNA virus that is a member of the *Hepadnaviridae* family. It is a highly contagious virus, spread by exposure to infectious blood and body fluids. Infection leads to liver inflammation (“hepatitis”), vomiting, jaundice, and occasionally death. It is common for infected individuals to become carriers of hepatitis B, meaning that infection remains active. Hepatitis B is associated with cirrhosis of the liver and hepatocellular carcinoma. It is estimated that one-third of the world’s population has been infected with hepatitis B, and that over 350 million people are chronic carriers (Chen, 2010). Given the causal associations between hepatitis B and mortality, development of an antiviral vaccine was a major public health priority.

The first vaccine licensed for human use for hepatitis B was a purified plasma preparation from patients with active hepatitis B infection. These individuals had high concentrations of hepatitis B proteins in serum, and purification of these proteins (including formalin inactivation) allowed their use as a vaccine. This vaccine was licensed in the early 1980s and administered by intramuscular route in a three-dose series (Szmuness et al., 1981). Although this vaccine was safe and effective, and seemed free of any exogenous agents, the need to purify the vaccine proteins from the serum of hepatitis B-infected individuals was problematic. The advent of technologies to produce cloned, recombinant proteins for immunization purposes led to the discontinuation of this product in favor of a recombinant vaccine. This vaccine was based on expression of a cloned recombinant form of hepatitis B surface antigen (HBsAg), expressed in the yeast *Saccharomyces cerevisiae*. A variety of manufacturers currently market licensed hepatitis B vaccines. These are recommended as universal vaccines for all newborns, administered by intramuscular route at 0, 1, and 6 months

of age. Individuals who miss immunization in infancy should be vaccinated with a three-dose series as soon as is feasible. Some manufacturers will provide hepatitis B vaccine as a component of a “mixture” of other common childhood vaccines, to help minimize the total number of required injections. The vaccine is adjuvanted with aluminum hydroxide. The mechanism of action of vaccination appears to be the induction of IgG antibodies targeting the HBsAg, with an antibody response of at least 10 mIU ml⁻¹ standing as a serological correlate of protection.

Human papillomavirus vaccine

Human papillomaviruses (HPVs) are common: there are at least 180 HPV genotypes described to date (Stanley, 2012). They are small, single-stranded, nonenveloped viruses that have a predilection for infection at mucosal or cutaneous surfaces. Most infections are asymptomatic, although many serotypes are associated with benign epithelial proliferation leading to warts. The major medical significance of HPV, however, stems from the fact that some subtypes are causally associated with malignancies of the anogenital track, particularly cervical carcinoma. Head and neck malignancies, respiratory papillomatosis, and anogenital warts are also caused by HPV infection. Worldwide, there are estimated to be approximately 530,000 new cases of HPV-associated cervical cancer per year, and 275,000 deaths (Tay, 2012).

There are approximately 15 HPV types that have been associated with anogenital malignancies; of these, HPV16 and HPV18 are the most prevalent, causing about 70% of cervical and anogenital cancer cases worldwide (Bosch et al., 2008). HPV6 and HPV11 are the types most commonly associated with genital warts (Lacey et al., 2006). There are two HPV vaccines currently licensed for clinical use. Both vaccines are based on the approach of generating noninfectious “virus-like particles” (VRPs) using recombinant technologies to express HPV proteins, which then spontaneously assemble into VRPs (Wang and Roden, 2013). The first licensed vaccine in the United States was a quadrivalent vaccine, based on VRPs cloned using recombinant technologies and synthesized in *S. cerevisiae*, and corresponding to HPVs 6, 11, 16, and 18. This vaccine is mixed with an aluminum hydroxide-based adjuvant prior to administration. The other licensed HPV vaccine is a bivalent vaccine, made up of VRPs corresponding to HPV16 and HPV18, and expressed in a recombinant baculovirus system prior to mixing with a monophosphoryl-lipid A-derived adjuvant. Both vaccines are extraordinarily effective at preventing HPV-associated malignancies as well as urogenital warts. The vaccines are administered by the intramuscular route, in a three-dose series commencing at age 9 years. The quadrivalent vaccine is currently recommended for boys and girls, whereas the bivalent vaccine (containing only the HPV types associated with cervical cancer) is recommended for girls only. The mechanism of protective immunity appears to be the induction of IgG antibody. The recent observation that there is cross-protective immunity induced by vaccination against nonvaccine strains provides optimism that these vaccines will protect against disease caused by diverse HPV types (Draper et al., 2013).

Inactivated influenza vaccine

Subunit, killed influenza virus vaccines have been in use for many decades in the United States. These vaccines are based on formalin inactivation of influenza viruses cultivated in fertilized eggs. Since the inactivation process kills the flu virus, it is impossible (and biologically inconceivable) that an individual could “get the flu” by being immunized. Typically, three strains are selected for cultivation (two strains of influenza A and one strain of influenza B), depending upon what strains have been observed circulating in the human population in recent outbreaks. Following formalin inactivation, enriched components of the virion are purified, and these so-called “split virion” component vaccines are administered in a single intramuscular injection annually prior to the onset of influenza season. Recently, an increasing number of pharmaceutical manufacturers have produced and marketed inactivated influenza vaccines. Some recent innovative vaccines that have either been licensed or are approaching licensure include vaccines manufactured in cell culture, rather than eggs, to avoid the issue of egg allergy (Brokhof et al., 2013); quadrivalent influenza vaccines capable of providing protection against two strains of influenza B in addition to two strains of influenza A (Ambrose and Levin, 2012); vaccines containing antigens generated using cloned, recombinant technologies (Sedova et al., 2012); vaccines using adjuvants to enhance the potency and effectiveness of influenza immunogens (Even-Or et al., 2013); and the development of vaccines expressing influenza immunogens as mRNA vaccines, analogous to the success that has been realized by COVID-19 mRNA vaccines (Scorza and Pardi, 2018). Given the disappointing performance of the past generations of influenza vaccines in controlling annual disease outbreaks (Osterholm et al., 2012), such advances and improvements are greatly needed (Atmar and Keitel, 2020).

Inactivated polio vaccine

As noted earlier in the section on oral, live, attenuated polio vaccines, the killed, inactivated IPV was actually the first vaccine against polio infection licensed in the United States (Melnick, 1996). The Salk vaccine was licensed in 1955, and the impact was immediate and dramatic. The total annual number of polio cases fell from 35,000 in 1953 to only 161 cases in 1961 (Hinman, 1984). In spite of this success, IPV was replaced by OPV in the early 1960s, due to the added benefits conferred by contact immunity, ease of administration (oral vs intramuscular), and lower cost. When it became clear by the 1990s that there was no longer any circulating wild-type poliovirus in the United States, and in fact that the only paralytic polio observed was VAPP caused by neurorevertant OPV, IPV once again became the vaccine of choice.

The IPV vaccine is administered by intramuscular or subcutaneous route. A four-dose series in childhood is recommended. There is no intestinal or mucosal immunity to IPV, in contrast to OPV. The mechanism of action is the induction of IgG antibodies capable of neutralizing the virus and protecting the central nervous system against paralytic polio. There is no contact immunity conferred by IPV immunization, although both IPV and OPV can produce “herd immunity” in a population if vaccination compliance is sufficient.

COVID-19 vaccines

The advent of the COVID-19 pandemic necessitated an urgent response, toward the goal of developing an effective vaccine against the SARS-CoV-2 virus. In response to this global crisis, a wide range of vaccine candidates have been developed. These range from nucleic acid based vaccines (DNA and RNA vaccines); live, attenuated vaccines; protein subunit vaccines; and vectored vaccines (Fiolet et al., 2021). In the United States, three vaccines have been licensed: two of these, BNT162b2 and mRNA-1273, are lipidated nanoparticle mRNA vaccines targeting the SARS-CoV-2 “Spike” protein, whereas the third vaccine, Ad26.COV2.S COVID-19, delivers the Spike open reading frame in the context of a replication-incompetent Adenovirus 26 vector. These vaccines have been remarkably effective in reducing COVID-19 infection, disease, hospitalization, and mortality. A major challenge for the future will be to continue to update vaccine design in response to emerging COVID-19 variants, such as the B.1.617.2 (Delta) SARS-CoV-2 variant (Cosar et al., 2021) and the B.1.1.529 (Omicron) variant (Saxena et al., 2021).

Viral vaccines and vaccine safety

In recent years, considerable attention has been given to the concern that vaccines, particularly the live, attenuated MMR vaccine, might be related to the development of autism in young children. Autism is a pervasive developmental disorder characterized by impaired social interaction, difficulties with verbal and nonverbal communication, and oftentimes stereotypical, repetitive patterns of behavior. It has become clear over recent years that the reports linking the MMR vaccine to autism were the product of flagrant scientific misconduct and clear-cut fraud (Flaherty, 2011). MMR and other vaccines have been demonstrated repeatedly to be safe and effective and no causal links have been found, in spite of exhaustive study, to link any childhood vaccine to autism or autism spectrum disorders (Gerber and Offit, 2009). A popular argument of the antivaccine movement is that the advent of new vaccines has created a state of “immune system overload” in children, by exposing them to too many antigens, too early in life. However, both the biological implausibility of this statement, as well as the fact that children today are in fact exposed to fewer total antigens in vaccines than they were in the 1960s (Offit et al., 2002), make this hypothesis completely untenable. Of even greater concern is the misinformation that has been promulgated about the safety of COVID-19 vaccines. Vaccine misinformation has contributed significantly to vaccine under-utilization, and this in turn has contributed to the sustenance of the COVID-19 pandemic globally (Ullah et al., 2021).

Priorities for new viral vaccines

Antiviral vaccines represent one of the most striking “success stories” in the history of medicine, having reduced (and in the case of smallpox, eliminated) the threat of many common, disabling, and even fatal virus infections. However, the vaccine armamentarium against serious viral infections is woefully incomplete and much work remains to be done. After the urgent need for continued optimization and implementation of COVID-19 vaccines, arguably the next most important – but to date elusive – target for vaccine development among viral infections is a vaccine for HIV, which continues to exact high levels of mortality in much of the world (Voronin et al., 2010). The most common vector-borne viral disease in the world is Dengue Fever, an infection that causes considerable morbidity and mortality, particularly in children. Although a Dengue vaccine has been licensed, its use is problematic (Wang et al., 2021). Prevention of dengue infection is a high priority for antiviral vaccine development (Lim et al., 2013). Hepatitis C infection is a common cause of liver failure as well as liver cancer, and a vaccine against this virus would represent an important public health advance (Voronin et al., 2010). Congenital infection (infection acquired by the developing fetus before birth) with cytomegalovirus is the most common infectious cause of birth defects, including hearing loss and developmental delay, in the United States. Development of a vaccine against this virus has therefore been designated as a major public health priority (Sung and Schleiss, 2010; Schleiss et al., 2017). Improved vaccines for influenza are needed, and a vaccine against respiratory syncytial virus is a high priority. This list is by no means exhaustive, but only serves to highlight a few of the many virus infections for which vaccines are still needed. In addition to these pathogens that require novel vaccines, improved vaccine delivery technologies are required. Vectored approaches, such as those offered by modified Vaccinia Virus Ankara and recombinant Vesicular Stomatitis Virus, are in clinical trials, and results are eagerly awaited. Nanoparticle vaccines also hold promise for improving immune responses for many “difficult” viral pathogens. Finally, scientists and clinicians need to be zealous advocates for immunization programs, in order to combat the untruthful agenda of the various organized antivaccine organizations. The field of antiviral vaccines greatly needs financial resources (Lindley et al., 2009), both from industry and government funding agencies, and more importantly the commitment of young investigators interested in research that will provide a tremendous “return on investment” in promoting the health of the population for future generations.

Introduction

Antimicrobial resistance continues to pose a significant global health threat (Prestinaci et al., 2015), as such new and novel antibacterial agents are urgently needed to combat antibiotic resistance and provide effective and safe therapeutic options for treating difficult-to-treat infections. In 2019, the US Centers for Disease Control and Prevention (CDC) released the second antimicrobial resistance threat report, which listed carbapenem-resistant *Acinetobacter*, *Candida auris*, *Clostridioides difficile* (*C. difficile*), carbapenem-resistant Enterobacterales (CRE), and drug-resistant *Neisseria gonorrhoeae* (*N. gonorrhoeae*) under the urgent threat category (CDC, 2019). Some serious threat pathogens include extended-spectrum β -lactamase (ESBL)-producing Enterobacterales, vancomycin-resistant *Enterococcus* (VRE), multidrug-resistant (MDR) *Pseudomonas aeruginosa* (*P. aeruginosa*), methicillin-resistant *Staphylococcus aureus* (*S. aureus*) (MRSA), drug-resistant *Streptococcus pneumoniae* (*S. pneumoniae*), and drug-resistant tuberculosis, etc. (CDC, 2019). Each year, there are >700,000 deaths worldwide from drug-resistant infections (Dadgostar, 2019); and in the US, there are an estimated 2.8 million antibiotic-resistant infections, leading to >35,000 deaths annually (CDC, 2019). Since 2000, thirty-six antibiotics have been approved by the US Food and drug administration (FDA), which include new chemotype antibacterial classes such as oxazolidinone, lipocyclopeptide, the cephalosporin-siderophore conjugate antibiotic, narrow-spectrum anti-difficile 18-membered macrolide and antitubercular diarylquinoline and nitroimidazooxazine. The remaining approved antibiotics were largely derived from existing antibacterial classes (e.g., carbapenem, quinolone, tetracycline, lipoglycopeptide, and cephalosporin) to improve clinical efficacy, bacterial spectrum, and/or safety and resistance profiles. In addition, several β -lactam/ β -lactamase inhibitor (BLI) combinations and three monoclonal antibodies (mAbs) have also been developed and approved during this period. Several excellent reviews have been published to cover recent FDA approved antibiotics and/or new antibacterial agents under clinical development, in the contexts of more clinical or chemistry driven setting (Butler and Paterson, 2020; Butler et al., 2013, 2017; Deak et al., 2016). In this book chapter, we systematically review and discuss their clinical applications and medicinal chemistry properties of these approved antibiotics from 2000 to 2021 (Hori et al., 2021).

FDA approved antibiotics since 2000

Thirty-six antibiotics have been approved by US FDA since 2000. These new antibiotics include new chemotype antibacterial classes such as oxazolidinone (linezolid and tedizolid phosphate), lipocyclopeptide (daptomycin), anti-difficile macrolide (fidaxomicin), the cephalosporin-siderophore conjugate antibiotic (cefiderocol), and antitubercular agents diarylquinoline and nitroimidazooxazine (bedaquiline and PA-824, respectively). The remaining advanced antibiotics, developed on the basis of existing antibacterial chemical classes, include carbapenem (ertapenem and doripenem), nitroimidazoles (tinidazole and secnidazole), fluoroquinolones (gemifloxacin mesylate, besifloxacin, delafloxacin, and flaxloxacina), ketolide (telithromycin), rifamycin (rifaximin and rifamycin SV), tetracycline and/or glycylcycline (tigecycline, eravacycline, omadacycline, and sarecycline), pleuromutilins (retapamulin and lefamulin), lipoglycopeptides (telavancin, oritavancin, and dalbavancin), cephalosporin (ceftaroline fosamil), aminoglycoside (plazomicin), four β -lactam/BLI combinations (ceftolozane/tazobactam, ceftazidime/avibactam, meropenem/vaborbactam, and imipenem/cilastatin/relebactam with a renal dehydropeptidase inhibitor), along with three monoclonal antibodies (mAbs) (raxibacumab, obiltoxaximab, and bezlotoxumab). All the approved antibiotics from 2000 to 2021 are presented based on the order of their approval date. The overview, key attributes, physiochemical properties and pharmacokinetic (PK) parameters of these FDA approved antibiotics are listed in Table 1. The chemical structures are shown in Figs. 1–4.

Zyvox® (linezolid)

Zyvox (linezolid) (Fig. 1), an oxazolidinone antibiotic from Pfizer, is the first medication of the oxazolidinone class, and was approved for use by the US FDA in 2000 (Lexicomp, 2021). It is indicated for nosocomial pneumonia, community acquired pneumonia (CAP), uncomplicated skin and skin structure infections (SSTIs), complicated SSTIs, and infections secondary to vancomycin-resistant *Enterococci* (VRE), caused by pathogens such as *Staphylococcus aureus* (including MRSA), *S. pneumoniae*, *S. pyogenes*, or *S. agalactiae* (Pfizer, 2020b). In addition to the FDA approved indications, linezolid is used in multidrug regimens for the treatment of multidrug-resistant tuberculosis (MDR-TB). The 2016 WHO treatment guidelines for drug-resistant TB designated linezolid as a second line treatment option for MDR-TB (WHO, 2016).

Linezolid is a synthetic, bacteriostatic antibiotic, and active against drug-resistant staphylococci, enterococci, streptococci, and certain Gram-negative and anaerobic bacteria (Pfizer, 2020b). Linezolid is not used clinically for the treatment of Gram-negative bacteria. Structurally, linezolid contains a 5-membered oxazolidinone heterocyclic ring with a cyclic carbamate functionality, as well as the S-stereochemistry at the 5 position and the phenyl ring at the three position, which are essential for antibacterial activity (Barbachyn and Ford, 2003). Linezolid inhibits bacterial ribosomal protein synthesis at very early stage by binding to the 23S ribosomal RNA of the 50S ribosomal subunit (Livermore, 2003; Moellering, 2003).

Linezolid is administered by the oral or parenteral route, and the dosage for adult patients with nosocomial pneumonia, CAP, cSSSI, and VRE infections including concurrent bacteremia is 600 mg IV or oral every 12 h for 10–14 days except VRE for 14–28 days; uncomplicated SSSI is 400 mg oral every 12 h for 10–14 days (Pfizer, 2020b). The oral bioavailability of linezolid is almost 100%, hence there is no dose adjustment when switching from the IV to PO route. Its plasma elimination half-life ranges from 3.4 to 7.4 h, and protein binding is approximately 31% (Dryden, 2011; Lexicomp, 2021). Linezolid is minimally metabolized via the cytochrome P450 enzymes, and contraindicated to take linezolid concomitantly with monoamine oxidase inhibitors (MAOIs) or within 2 weeks of the MAOI use. The most common adverse reactions reported in >5% of patients who take linezolid are diarrhea, vomiting, headache, nausea and anemia (Pfizer, 2020b). Patients taking linezolid should be monitored for myelosuppression (weekly complete blood counts), peripheral and optic neuropathy (symptoms of visual impairment) in patient on linezolid for >28 days, serotonin syndrome in those taking serotonergic agents, *Clostridioides difficile*-associated diarrhea (CDAD), and hypoglycemia in diabetic patients on insulin or antidiabetic medications (Pfizer, 2020b).

Invanz® (ertapenem)

Invanz (ertapenem) (Fig. 1) was approved by the US FDA for the treatment of moderate to severe infections due to susceptible bacteria in 2001. Currently approved indications of Invanz include complicated intra-abdominal infections (cIAI), pelvic infection, CAP, cSSSI, and complicated urinary tract infections (cUTI), as well as surgical prophylaxis to prevent infections after colorectal surgery (Merck, 2020a). Ertapenem showed bactericidal and broad-spectrum antibacterial activity against Gram-negative organisms such as ESBL- and AmpC-producing *Enterobacteriaceae*, Gram-positive and anaerobic bacteria (Keating and Perry, 2005). Ertapenem is not active against MRSA and *Enterococcus* spp., and Gram-negative *Acinetobacter* and *Pseudomonas* spp. (Livermore et al., 2003).

Ertapenem, bearing with 3-(carboxy phenyl amino carbonyl)pyrrolidinyl thio, 4 β -methyl, and 6-substituted 1R-1-hydroxyethyl motifs, belongs to the carbapenem chemical class among the broad family of β -lactam antibiotics. It inhibits bacterial cell wall synthesis by binding to PBP and subsequently leads to bacterial cell lysis (Papp-Wallace et al., 2011). Similar to other carbapenems, ertapenem is resistant to β -lactamases because of the 1R-1-hydroxyethyl substituent at the 6-position (Fig. 1); in addition, the 4 β -Me group shields the β -lactam carbonyl moiety, thereby minimizing hydrolysis catalyzed by renal dehydropeptidase (DHP)-1 (Hammond, 2004). Furthermore, ertapenem is unique with a *meta*-benzoic acid motif which improves the molecule's lipophilicity

Table 1 Key attributes, physiochemical properties and PK parameters (Lexicomp, 2021) of FDA approved antibiotics since 2000.

Antibiotic	Chemical class	MoA	MW (g/mol)	logP	HBA	HBD	PSA (Å²)	RoA and dosing frequency	T _{max} [t _{1/2}] (h)	Bioavailability (%)	Protein binding (%)	Metabolism	Excretion (%)		Developed and/or marketed by	Initial US Approval (M/D/Y)
													Urine	Feces		
Zyvox (linezolid)	Oxazolidinone	Protein synthesis inhibitor by binding to the 23S rRNA of the bacterial 50S ribosomal subunit	337.35	0.45	7	1	71	IV, PO 400, 600 mg every 12 h	1–2 h [4.9 h]	100 (PO)	31	Hepatic oxidation (minimal)	30 (P), 50 (M)	9 (M)	Pfizer Inc.	4/18/2000

Zemdri (plazomicin)	Aminoglycoside	Protein synthesis inhibitor by binding to the bacterial 30S ribosomal subunit	592.68	−3.83	16	14	269	IV 15 mg/kg (once-daily)	Just after infusion [3–4 h]	20		97.5 (P)	<0.2	Cipla USA Inc.	6/26/2018	
Xerava (eravacycline)	Tetracycline	Protein synthesis inhibitor by binding to the bacterial 30S ribosomal subunit	558.56	2.55	12	7	194	IV (pH: 5.5–7) 1 mg/kg (every 12 h)	[20 h]	79–90	Oxidation via CYP3A4 and FMO	20 (P), 14 (M)	17 (P), 30 (M)	Tetraphase Pharmaceuticals Inc.	8/27/2018	
Seysara (sarecycline)	Tetracycline	Protein synthesis inhibitor by binding to the bacterial 70S ribosomal subunit	487.50	−0.04	11	6	174	PO 60, 100, or 150 mg (once-daily)	1.5–2 h [21–22 h]	62.5–74.7	Minimal (<15%) in vitro	24.7 (P), 19.4 (M)	14.9 (P), 27.7 (M)	Almirall, LLC	10/2/2018	
Nuzyra (omadacycline)	Tetracycline (aminomethylcycline)	Protein synthesis inhibitor by binding to the bacterial 30S ribosomal subunit	556.65	1.85	11	7	177	IV 200 mg on day 1, then 100 mg; PO 450 or 300 mg on days 1 and 2, then 300 mg (once-daily)	IV 0.5 h [16 h]; PO 2.5 h [13.45–16.83 h]	34.5 following a single-dose 300 mg	20	Not metabolized	IV: 27 (P); PO: 14.4 (P)	PO: 77.5–84.0 (P)	Paratek Pharmaceuticals, Inc.	10/3/2018
Aemcolo (rifamycin SV)	Rifamycin	Protein synthesis inhibitor by binding to the β-subunit of bacterial DNA-dependent RNA polymerase	697.77	1.52	13	6	201	PO 388 mg (twice-daily)		<0.1	80		86	Aries Pharmaceuticals, Inc.	11/19/2018	
Recarbrio (imipenem/cilastatin/relebactam)	Carbapenem combination	Penicillin-binding protein inhibitor/renal dehydropeptidase inhibitor/β-lactamase inhibitor	299.35/358.45/348.38	−2.95/0.74/−1.45	7/7/10	4/5/3	139/155/137	IV 1.25 g (every 6 h)	Imipenem [1 h] relebactam [1.2 h]		20/40/22	Metabolized by dehydropeptidase I (kidney)/prevent imipenem metabolism/ minimally metabolized	63/77/>90 (P)		Merck & Co, Inc.	7/17/2019
Pretomanid (PA-824)	Nitroimidazooxazine	Mycolic acid biosynthesis inhibitor; a respiratory poison by releasing nitric oxide	359.26	3.11	8	0	91.3	PO 200 mg (once-daily)	4.5 h [16 h]		86.4	Reduction/oxidation; 20% (CYP3A4)	1 (P), 52 (M)	38	TB Alliance/ Mylan Specialty LP	8/14/2019
Xenleta (lefamulin)	Pleuromutilin	Protein synthesis inhibitor by binding to the 23S rRNA of the bacterial 50S ribosomal subunit	507.73	2.80	6	4	135	IV 150 mg, PO 600 mg (every 12 h)	PO 0.88–2 h [3–20 h]	25	94.8–97.1	Primarily CYP3A4	IV: 15.5 (9.6–14.1, P); PO: 5.3	IV: 77.3 (4.2–9.1, P); PO: 88.5 (7.8–24.8, P)	Nabriva Therapeutics	8/19/2019
Fetroja (cefiderocol)	Cephalosporin siderophore	Penicillin-binding protein inhibitor with enhanced cell entry via iron uptake system	752.22	−1.02	17	8	310	IV (pH 5.2–5.8) 2 g (every 8 h)	[2–3 h]		40–60	Minimal	90.6 (P), 8 (M)	2.8	Shionogi Inc.	11/14/2019
Abthrax (Raxibacumab)	mAb	binds and neutralizes free protective antigen component of <i>B. anthracis</i> toxin	146 kDa					IV (pH 6.5) 40 mg/kg (a single-dose)	[20.44 days]			Nonrenal			GlaxoSmithKline	12/14/2012
Anthim (oblitoxaximab)	mAb	binds free protective antigen component of <i>B. anthracis</i> toxin	148 kDa					IV 16 or 24 mg/kg (a single-dose)				Minimal renal elimination			Elusys Therapeutics, Inc	3/18/2016
Zinplava (bezlotoxumab)	mAb	binds and neutralizes to <i>C. difficile</i> toxin B	148.2 kDa					IV (pH 6) 10 mg/kg (a single-dose)	[19 days]		Metabolized via catabolism	Primarily through catabolism			Merck & Co., Inc.	10/21/2016

Lipinski properties were obtained from Scifinder and calculated using Advanced Chemistry Development (ACD/Labs) Software V11.02 (© 1994–2021 ACD/Labs). MW refers to the molecular weight of the free acid or base drug form. HBA, hydrogen bond acceptor; HBD, hydrogen bond donor; PSA; polar surface area.

All PK parameters refer to adults unless otherwise noted. PO, by mouth or oral. IV, intravenous.

Under excretion: P refers to approximate % of total dose as parent drug and M refers to approximate % of total dose as metabolites. DSC, discontinued (brand name and/or generic product in the US).

Fig. 1 Chemical structures of FDA approved antibiotics from 2000 to 2005.

profile with a net negative charge under physiological pH, allowing for once daily dosing with an extended elimination plasma half-life resulting from high protein binding 85–95% (Hammond, 2004).

Invanz (ertapenem) is available in a single-dose vial as a powder (1 g), and can be administered both IM or IV. It requires reconstitution and/or further dilution before IV infusion or IM injection (Merck, 2020a). For patients ($\text{CrCl} > 30 \text{ mL/min/1.73 m}^2$), Invanz 1 g is infused daily over 30 min or injected via IM; and the duration of treatment varies from days to weeks, depending on the type and severity of infections (Merck, 2020a). Dosage adjustment to 500 mg daily is required for patients with severe renal dysfunction ($\text{CrCl} \leq 30 \text{ mL/min/1.73 m}^2$) and end-stage renal disease ($\text{CrCl} \leq 10 \text{ mL/min/1.73 m}^2$). The most common adverse effects occurring in at least 5% of patients on Invanz include diarrhea, nausea, headache, and infused vein complication (Lexicomp, 2021). As a broad-spectrum parenteral carbapenem antibiotic, ertapenem serves as an alternative therapeutic option for the treatment of patients with complicated bacterial infections.

Factive® [DSC] (gemifloxacin)

Factive (gemifloxacin) (Fig. 1), a member of fluoroquinolone antibiotics, was approved by the US FDA for the treatment of CAP and acute bacterial exacerbation of chronic bronchitis (ABECB) in 2003 (Lexicomp, 2021). It is effective toward mild-to-moderate respiratory tract infections due to susceptible pathogens. Gemifloxacin showed potent and broad-spectrum activities against Gram-positive and Gram-negative microorganisms such as MDR *S. pneumoniae* and other bacterial strains (Ball et al., 2004).

Gemifloxacin is a fourth generation, oral synthetic fluoroquinolone derivative with 3-aminomethyl-4(Z)-methoxyimino-1-pyrrolidinyl and cyclopropyl motifs at the C7 and N1 positions, respectively. It works as a DNA gyrase and topoisomerase IV inhibitor. The enhanced activity of gemifloxacin against both DNA gyrase and topoisomerase IV, and anaerobes, is attributed to the introduction of nitrogen at the 8 position (Pham et al., 2019).

Factive used to be available as tablets containing 320 mg of gemifloxacin and is taken orally with or without food once daily for a period of treatment 5–7 days (FDA, 2019b). The dose of gemifloxacin is reduced to 160 mg daily in patients with $\text{CrCl} \leq 40 \text{ mL/min}$. The most common adverse events reported in at least 3% of patients on Factive include headache, rash, diarrhea, nausea, and increased serum alanine aminotransferase (FDA, 2019b). Factive (gemifloxacin) carries boxed warnings of serious adverse reactions and exacerbation of myasthenia gravis; and is no longer available in the US (Lexicomp, 2021). Fluoroquinolones were reported to cause some rare, but serious adverse effects including tendinopathy and tendon rupture, peripheral neuropathy, and CNS effects (Marchant, 2018).

Cubicin® (daptomycin)

Cubicin (daptomycin) (Fig. 1), the first antibiotic of the cyclic lipopeptide drug class, was approved by the US FDA in 2003. Daptomycin is indicated for use in adult and pediatric patients with cSSSIs due to Gram-positive pathogens (e.g., vancomycin-susceptible *E. faecalis*, MSSA and MRSA, *S. pyogenes*, *S. agalactiae*, and *S. dysgalactiae*). Daptomycin is also approved for treating adult patients with bacteremia, including right-sided infective endocarditis due to MSSA and MRSA (Merck, 2021a). Daptomycin showed activity against a wide-spectrum of aerobic and anaerobic Gram-positive bacteria including strains of MRSA and VRE (Vilhena and Bettencourt, 2012).

Mechanistically, daptomycin exerts its concentration-dependent bactericidal effects by disrupting the integrity of the cell membrane of susceptible Gram-positive pathogens (Taylor and Palmer, 2016). Daptomycin also possesses a notable postantibiotic effect of up to 6 h (Vilhena and Bettencourt, 2012). Daptomycin interacts with the bacterial lipid membrane through calcium-dependent insertion of the long lipid side chain (Carpenter and Chambers, 2004). Disruptions such as conformational changes of daptomycin and oligomerization, formation of pores, and lipid flip-flop cause leaks in the cell membrane, the release of intracellular ions, and cell death (Sauermann et al., 2008). Daptomycin does not work in Gram-negative bacteria as it is not able to get through the outer membrane (Carpenter and Chambers, 2004). Daptomycin can be inactivated by pulmonary surfactant and therefore should not be used in patients with pneumonia or other respiratory diseases (Silverman et al., 2005). Daptomycin, a fermentation product of *Streptomyces roseosporus*, contains 13 D- and L-amino acids in total, a macrocyclic decapeptide scaffold linked by a lactone functionality between the kynurenine residue and threonine, as well as a tripeptide side chain with a 10-carbon fatty acid tail (Penn et al., 2006). Although daptomycin has a high water solubility as it is primarily acidic and negatively charged at neutral pH, it also possesses amphipathic characteristics due to the presence of hydrophobic lipid side chain as well as hydrophilic peptide moieties (Vilhena and Bettencourt, 2012).

Daptomycin is available as a lyophilized powder that requires reconstitution before administration as an IV infusion over 30 min or as an IV push over 2 min. Vigorous shaking of the vial should be avoided after reconstitution of daptomycin to prevent foaming (Merck, 2021a). The approved dose of daptomycin to treat patients with bacteremia (including right-sided infective endocarditis) due to *S. aureus* is 6 mg/kg IV once daily for a duration of 2–6 weeks (Merck, 2021a). For patients (CrCl $\geq$ 30 mL/min) with cSSSIs, daptomycin 4 mg/kg IV should be administered once daily for a duration of 7–14 days. For right-sided endocarditis of a native valve, daptomycin 6 mg/kg IV should be administered once daily for a duration of 2–6 weeks (Merck, 2021a). When daptomycin is used in patients with renal dysfunction (CrCl $<$ 30 mL/min), the dosage must be adjusted (Carpenter and Chambers, 2004). The most common adverse effects reported in more than 6% of patients on daptomycin include chest pain, edema, infection due to Gram-negative pathogens, insomnia, and pharyngolaryngeal pain (Merck, 2021a). Daptomycin is indicated for the treatment of patients with cSSSIs, bacteremia, and right-sided infective endocarditis due to susceptible Gram-positive bacteria; it also serves as a valuable treatment option for other Gram-positive and difficult-to-treat infections (Gonzalez-Ruiz et al., 2016).

Ketek® [DSC] (telithromycin)

Ketek (telithromycin) (Fig. 1), the first ketolide antibiotic, was approved by the US FDA in 2004 for use in adult patients with mild to moderate CAP, caused by susceptible and MDR *S. pneumoniae*, *Chlamydophila pneumoniae*, *H. influenzae*, *Moraxella catarrhalis*, or *Mycoplasma pneumoniae* (Ketek, 2015). Telithromycin, a member of the macrolide-lincosamide-streptogramin B (MLS_B) resistance family, possesses activity against resistant Gram-positive and common respiratory pathogens (Ketek, 2015; Kasbekar and Acharya, 2005).

Telithromycin inhibits bacterial protein synthesis by binding to two sites, domains II and V of the 23S rRNA of the 50S ribosomal subunit (Kasbekar and Acharya, 2005). Although the structure of telithromycin is similar to that of erythromycin, the macrolide antibiotic, telithromycin has several unique structural modifications. Instead of a cladinose sugar at position 3, telithromycin displays a ketone moiety. This structural feature increases the stability of telithromycin in acidic environments, improves its activity against pathogens that are resistant to macrolide antibiotics, and also plays a role in preventing telithromycin induced resistance to MLS_B (Kasbekar and Acharya, 2005; Nguyen and Chung, 2005). Compared to a hydroxyl group, the 6-MeO functionality enhances the compound's stability in acidic environments (Nguyen and Chung, 2005). Telithromycin also possesses a cyclic carbamate ring motif fused at the C-11 and C-12 positions with an extended butyl-imidazole-pyridine side chain (Lonks and Goldmann, 2005). This structural feature of telithromycin contributes to its strong affinity for domain II of the bacterial 50S ribosomal subunit, conferring activity against MLS_B-resistant pathogens. In addition, telithromycin is able to retain activity against antibiotic-resistant pathogens due to the methylase or efflux pumps (Kasbekar and Acharya, 2005; Lonks and Goldmann, 2005).

For patients with CAP, the dose of telithromycin is 800 mg, given orally once-daily for 7–10 days (Lexicomp, 2021). Telithromycin is contraindicated in myasthenia gravis patients due to reported fatal and life-threatening respiratory failure in this patient population (Ketek, 2015). Telithromycin affects medications that are metabolized by CYP3A4 as it is both a strong CYP3A4 inhibitor and substrate (Nguyen and Chung, 2005). The CYP3A4 enzyme inhibitors (e.g., ketoconazole and itraconazole) increase both the $C_{\max}$ and AUC of telithromycin (Ketek, 2015). This antibiotic can also prolong the QTc interval and should be used with caution when administered with other agents that also prolong the QTc interval (Kasbekar and Acharya, 2005). Telithromycin should not be used with hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, such as lovastatin, atorvastatin, or

simvastatin, as administration of these medications together can increase a patient's risk of experiencing myopathy (Nguyen and Chung, 2005). The most common adverse effects in $\geq 7\%$ of patients taking telithromycin are diarrhea and nausea. Patients with hepatic dysfunction do not need a dosage adjustment, but telithromycin should be discontinued immediately when any signs of hepatitis develop in patients taking telithromycin (Ketek, 2015). Telithromycin requires a dosage adjustment (600 mg once daily) in patients with severe renal dysfunction ($\text{CrCl} < 30 \text{ mL/min}$) or on hemodialysis (Kasbekar and Acharya, 2005). The brand name product Ketek of telithromycin has been discontinued in the US by the manufacturer since March 2016 due to business reasons (Lexicomp, 2021), among increased safety concerns and warnings related to severe liver injury (Ross, 2007).

Tindamax® [DSC] (tinidazole)

Tindamax (tinidazole) (Fig. 1), the second antibiotic in the 5-nitroimidazole drug class, is an antiprotozoal and antibacterial agent that was approved by the US FDA for use in 2004 (Dickey et al., 2009; Fung and Doan, 2005). The brand name product, Tindamax, has been discontinued in the US (Lexicomp, 2021). Tinidazole possesses activity against a majority of anaerobic pathogens including *Bacteroides fragilis* as well as the microaerophilic bacteria *H. pylori* and *Campylobacter* species (Fung and Doan, 2005). Tinidazole is indicated for uses in adult patients with trichomoniasis caused by *T. vaginalis*; in patients (≥ 3 years) with giardiasis due to *Giardia duodenalis* or *G. lamblia* as well as amebiasis or amebic liver abscess due to *Entamoeba histolytica*; and in adult women to treat bacterial vaginosis (FDA, 2020).

Tinidazole is a prodrug that is able to diffuse into the cells of susceptible pathogens, where the nitro group is then reduced by ferredoxin-mediated electron transport (Fung and Doan, 2005). This results in the production of toxic radicals, leading to tinidazole's cytotoxic effects. As tinidazole is metabolized inside the cells, its concentration decreases and the gradient allows for more entry of the tinidazole prodrug (Dickey et al., 2009). Structurally like metronidazole, tinidazole has a nitroimidazole motif, however, it contains a 2-(ethylsulfonyl)ethyl side chain instead of a 2-(hydroxyl)ethyl counterpart in metronidazole.

The generic tinidazole is available as 250 and 500 mg tablets (Lexicomp, 2021). The half-life of tinidazole is 12–14 h and is longer than that of metronidazole (8 h), enabling a shorter duration of treatment with tinidazole (Johnson, 2009). In adult patients with trichomoniasis or giardiasis, tinidazole 2 g as a single-dose treatment should be taken orally (Fung and Doan, 2005). Tinidazole 2 g once daily should be taken orally by adult patients for a duration of 3 days or 3–5 days in the treatment of intestinal amebiasis and amebic liver abscess, respectively. Adolescent and adult patients with bacterial vaginosis should take tinidazole 2 g orally once-daily for 2 days or tinidazole 1 g once-daily for 5 days (FDA, 2020; Johnson, 2009). For adolescent and pediatric patients older than 3 years with amebiasis, amebic liver abscess, giardiasis, or trichomoniasis, the treatment duration is the same as adult patients, but doses of tinidazole should be weight-based (50 mg/kg/day) with a maximum of 2 g daily (FDA, 2020). Tinidazole most commonly causes gastrointestinal (GI) adverse effects such as anorexia, dyspepsia, epigastric discomfort, nausea, metallic taste, as well as vomiting (Dickey et al., 2009). Tinidazole should be taken with food to decrease the occurrence of these adverse GI reactions (Johnson, 2009). Patients taking tinidazole should also avoid consuming alcohol for up to 3 days as a disulfiram-like reaction can occur. The label of tinidazole has a warning for neurologic adverse effects as convulsive seizure and paresthesia have been reported during treatment (FDA, 2020). Tinidazole is contraindicated in pregnant women and nursing mothers, breast-feeding should be stopped during tinidazole therapy and for 3 days after completing the therapy (FDA, 2020).

Xifaxan® (rifaximin)

Xifaxan (rifaximin) (Fig. 1), a member of the rifamycin drug class, was first approved by the US FDA in 2004 for use in patients older than 12 years of age to manage travelers' diarrhea due to noninvasive *E. coli* (Lexicomp, 2021). In 2010, it was approved by the US FDA to reduce overt hepatic encephalopathy recurrence in adult patients with advanced liver disease (Rivkin and Gim, 2011). Rifaximin was also approved by the US FDA in 2015 to treat adult patients with moderate to severe irritable bowel syndrome with diarrhea (IBS-D) (Lexicomp, 2021; Gupta et al., 2017). Rifaximin possesses a broad-spectrum activity against Gram-positive, Gram-negative, aerobic, and anaerobic bacteria, as well as protozoan pathogens (Koo and DuPont, 2010).

Rifaximin exerts its bactericidal effects by disrupting bacterial RNA synthesis via binding to the β subunit of DNA-dependent RNA polymerase (DdRp) (Koo and DuPont, 2010). Rifaximin also disrupts bacterial adhesion, internalization, and translocation, preventing pathogenic virulence. It also reduces the patient's inflammatory immune response and causes positive changes to the microbiota of the patient's GI system (Ponziani et al., 2017). Rifaximin is nonabsorbed when taken orally and thus has limited systemic side effects as its action is confined to the GI tract. Bacteria are able to develop rifaximin resistance due to the alteration of DdRp chromosomes (Rivkin and Gim, 2011).

Rifaximin is available as tablets in strengths of 200 or 550 mg and can be taken with or without food (Salix, 2020). When used to reduce overt hepatic encephalopathy recurrence, rifaximin 550 mg should be given twice daily (Rivkin and Gim, 2011). For travelers' diarrhea, rifaximin 200 mg should be given three times daily for 3 days (Koo and DuPont, 2010). Patients with IBS-D should be given rifaximin 550 mg three times daily for 14 days. If IBS-D symptoms occur again, the patient can be treated with the same dosing regimen up to two times (Salix, 2020). The dosage adjustment of rifaximin in patients with renal or hepatic impairment has not been studied or is currently no recommendations, partly due to its nonsystemic effect. However, rifaximin should be used with caution in patients with severe hepatic dysfunction (Salix, 2020). Adverse effects occur more commonly in

patients receiving rifaximin treatment to reduce overt hepatic encephalopathy recurrence. The most common adverse effects reported in at least 10% of patients on rifaximin for this indication are ascites, dizziness, fatigue, nausea, and peripheral edema (Salix, 2020). Rifaximin is a unique nonsystemic antibiotic derived from rifamycin, with a range of indications because of its wide antibacterial activity (Rivkin and Gim, 2011).

Tygacil® (tigecycline)

Tygacil (tigecycline) (Fig. 1), the first drug in the glycylcycline class with an expanded spectrum of antibacterial activity, was approved by the US FDA for use in 2005 (Pfizer, 2020a). This semisynthetic antibiotic can be used to treat patients with a wide range of infections as it possesses activity against aerobic Gram-positive and Gram-negative, as well as anaerobic pathogens (Noskin, 2005). Tigecycline is indicated to treat adult patients with CABP, cIAIs, and cSSSIs, caused by susceptible pathogens such as penicillin-susceptible *S. pneumoniae*, *E. coli*, *K. pneumoniae*, vancomycin-susceptible *E. faecalis*, MSSA/MRSA, *S. anginosus* group, and *S. pyogenes* etc. (Pfizer, 2020a).

Tigecycline exerts bacteriostatic effects and works by inhibiting bacterial protein synthesis via binding to the 30S ribosomal subunit (Noskin, 2005). This novel antibiotic overcomes some main tetracycline as well as other common antibiotic resistance mechanisms including ribosomal protection, target site modifications, and efflux pumps (Peterson, 2008). Tigecycline, a derivative of minocycline, possesses a linear four-ring carbocyclic skeleton, along with an additional 9-substituted *t*-butyl-glycylamido side chain on the D-ring. This addition causes steric hindrance, allowing tigecycline for evading common bacterial resistance mechanisms (Pankey, 2005).

Tigecycline is only available for parenteral use due to its limited oral bioavailability, and dosed twice daily as an IV infusion over 30–60 min (Pankey, 2005). For all of its indications, tigecycline 100 mg should be given once initially, followed by 50 mg IV administered every 12 h. For CABP, the treatment duration is 7–14 days. For cIAIs and cSSSIs, tigecycline should be given for 5–14 days (Lexicomp, 2021). For patients with renal dysfunction, there are no dosage adjustments required. However, patients with severe hepatic dysfunction (Child Pugh C) require dosage adjustments (tigecycline 100 mg initially, followed by 25 mg every 12 h) (Pfizer, 2020a). The most common adverse effects of tigecycline reported in over 10% of patients include diarrhea, nausea, and vomiting. Tigecycline has an FDA boxed warning (since 2013) for increased all-cause mortality (risk difference of 0.6%) (Pfizer, 2020a). Tigecycline is an expanded spectrum antibiotic that works against bacteria with resistance mechanisms to other classes of antibiotics, and is reserved as an alternative antibiotic for treating cSSSI, cIAI or CABP, caused by susceptible organisms (Pankey, 2005).

Altabax® (retapamulin)

Altabax (retapamulin) (Fig. 2) is a novel semisynthetic antibacterial agent from naturally occurring pleuromutilin antibiotic class, isolated from the edible mushroom, *Clitophilus scyphoides* (Williamson et al., 2017; Paukner and Riedl, 2017). The Canadian brand name Altargo 1% product for retapamulin has been discontinued, and this topical antibiotic Altabax (retapamulin) was approved by the US FDA for use in 2007 (Lexicomp, 2021). In the US, retapamulin is indicated for topical use in patients who are at least 9 months old with impetigo, caused by MSSA or *S. pyogenes* (Hartman-Adams et al., 2014; Williamson et al., 2017). Impetigo is a bacterial skin infection that can affect people of any age, but most commonly occurs in children who are 2 to 5 years old. Nonbullous impetigo, distinguished by honey-colored crusts appearing on the patient's face as well as extremities, is more common. Bullous impetigo, distinguished by the appearance of yellow fluid-containing flaccid bullae, occurs less often (Hartman-Adams et al., 2014). The FDA has not approved this topical antibiotic for use in nares for staphylococcal carrier treatment or for treating patients with MRSA-related skin infections (Hartman-Adams et al., 2014; Septimus and Schweizer, 2016).

Fig. 2 Chemical structures of FDA approved antibiotics from 2006 to 2010.

Retapamulin inhibits bacterial protein synthesis and exerts primarily bacteriostatic effects by binding to the 50S ribosomal subunit (Lexicomp, 2021). Retapamulin also works by inhibiting peptidyl transfer as well as P-site interactions to block the formation of active 50S ribosomal subunits (FDA, 2019a). In *S. aureus*, retapamulin resistances can occur due to mutations in the ribosomal protein L3 and the 23S rRNA gene, overexpression of efflux pumps or the chloramphenicol-florfenicol resistance (*cfr*) methyltransferase which disrupts bacterial interaction with retapamulin by methylating the 23S rRNA subunit (Williamson et al., 2017).

Retapamulin is available as a 1% (10 mg/1 g) ointment in 15 and 30 g tubes (FDA, 2019a). The ointment should be applied to the affected area two times a day for 5 days. In adults, the total applied area should not be greater than 100 cm², and in children, the total applied area should not be more than 2% of the patient's total body surface area (Hartman-Adams et al., 2014). Since the systemic absorption of retapamulin is low, adjustments based on renal or hepatic impairment are unlikely to be needed. The most common adverse effect reported in at least 2% of patients on retapamulin is application site reactions including irritation in adults as well as pruritus in infants, children, and adolescents (Lexicomp, 2021). At the time of approval in 2007, retapamulin represented the first new topical antibiotic approved for use in almost 20 years, and it is used topically for patients with impetigo (Hartman-Adams et al., 2014).

Doribax® [DSC] (doripenem)

Doribax (doripenem) (Fig. 2), a β -lactam parenteral antibiotic belonging to the carbapenem drug class, was approved by the US FDA in 2007; and is currently discontinued in the US (Lexicomp, 2021). Doripenem was active against Gram-positive, anaerobic, as well as enteric and nonenteric Gram-negative pathogens, including ESBL-producing strains (Chahine et al., 2010). In 2014, the US FDA approved changes in the doripenem label to include a warning for patients with VABP because of increased risk of death and lower clinical outcome (FDA, 2014a). Doripenem is indicated for use in adult patients with cAIs and cUTIs including pyelonephritis (Mathews and Lancaster, 2009). It should be used in cAIs due to pathogens such as *Bacteroides caccae*, *B. fragilis*, *B. thetaiotaomicron*, *B. uniformis*, *B. vulgatus*, *E. coli*, *K. pneumoniae*, *Peptostreptococcus micros*, *P. aeruginosa*, *S. intermedius*, and *S. constellatus*. Doripenem should be used in cUTIs as well as pyelonephritis, due to pathogens such as *A. baumannii*, *K. pneumoniae*, *E. coli*, *P. mirabilis*, and *P. aeruginosa* (FDA, 2015; Lexicomp, 2021).

Doripenem shows concentration-independent bactericidal activity and exerts its effects by disrupting the synthesis of bacterial cell walls (Chahine et al., 2010). Specifically, it inhibits the last transpeptidation step in the peptidoglycan synthesis by binding to PBPs such as PBP2-4, ultimately resulting in bacterial lysis (Lexicomp, 2021). Doripenem contains a 4 β -methyl group and an unsaturated bond C2=C3 at positions 2 and 3. These structural features differentiate doripenem from other penicillin antibiotics. At position 6, doripenem has a 1R-1-hydroxyethyl group, a structural motif commonly found in the carbapenem drug class and conferring β -lactamase resistance (Matthews and Lancaster, 2009). Moreover, doripenem is resistant to the enzyme hydrolysis in ESBL and AMPC-producing *Enterobacteriaceae*, in addition to most β -lactamases. Unlike imipenem, doripenem does not need to be given with the dehydropeptidase-1 inhibitor, cilastatin, because of the 4 β -methyl functionality and improved resistance to renal dehydropeptidase-1 (Matthews and Lancaster, 2009; Chahine et al., 2010). Doripenem also contains a bulky sulfamoylaminoethylpyrrolidinylthio side chain at the 3 position, which differentiates it from meropenem and provides the activity against Gram-negative, non-fermenting bacilli (Chahine et al., 2010).

Doripenem 500 mg, available in single-use 250 and 500 mg vials, should be given every 8 h as an IV infusion over 1 h to patients with cIAI and cUTI (CrCl of >50 mL/min) (Matthews and Lancaster, 2009). The dosage must be adjusted for patients with renal impairment (CrCl $\leq$ 50 mL/min) (Chahine et al., 2010). Patients should be given parenteral therapy for at least 3 days and exhibit signs of clinical improvement before switching to an oral antimicrobial therapy can be considered (FDA, 2015). The duration of treatment for patients with cIAI and cUTI is 10 days, and 5–14 days, respectively (Matthews and Lancaster, 2009). The most common adverse reactions reported in more than 10% of patients on doripenem include diarrhea, headache, and nausea (FDA, 2015). In 2013, the US FDA updated the doripenem label to include the risk of seizures as a warning, due to observed cases during treatment with doripenem (FDA, 2015), though the likelihood of doripenem-inducing seizures is relatively low (Chahine et al., 2010). The coadministration of doripenem and valproic acid may result in losing a patient's seizure control, due to reduced serum concentrations of valproic acid (Matthews and Lancaster, 2009).

Zeftera® (ceftobiprole medocaryl)

Zeftera (ceftobiprole medocaryl) (Fig. 2), a fifth-generation cephalosporin prodrug, was approved for use in Canada and many European countries for adult patients with CAP or HAP (David et al., 2017; Avirpharma, 2019), however both ceftobiprole and ceftobiprole medocaryl are not currently approved for use in the US or for ventilator-acquired pneumonia (VAP) (Lexicomp, 2021). Ceftobiprole belongs to the cephalosporin drug class and possesses a wide spectrum of antibacterial activity against Gram-positive and Gram-negative pathogens including MRSA and penicillin-resistant *S. pneumoniae* (Barbour et al., 2009). Ceftobiprole should be used to treat CAP and HAP due to pathogens such as *E. coli*, *H. influenzae*, *K. pneumoniae*, *S. aureus* including MRSA, as well as *S. pneumoniae*.

Ceftobiprole is a bactericidal antibiotic and works by disrupting the process of cell wall synthesis via binding to bacterial PBPs (David et al., 2017). It has strong affinity for PBP2a in MRSA, PBP2x in penicillin-resistant *S. pneumoniae*, and PBP2b in penicillin-intermediate *S. pneumoniae* and is active against these resistant pathogens; it is also able to bind to PBP1a and PBP2-4 in *E. coli* in addition to PBP1a-b, PBP3-4 in *P. aeruginosa* (Davies et al., 2007). Ceftobiprole also binds to PBP5 in *E. faecalis* (Dauner et al., 2010; Lexicomp, 2021). Ceftobiprole medocaryl, the water-soluble prodrug given via IV, is rapidly hydrolyzed in vivo to the active form, ceftobiprole, after administration (Barbour et al., 2009). Ceftobiprole, like other cephalosporin antibiotics, contains a characteristic cephem nucleus (a 4-membered β -lactam ring fused with a 6-membered, sulfur-containing, dihydrothiazine heterocycle), along with a pyrrolidinone-3-ylidene-methyl side chain at the 3 position (Dauner et al., 2010).

Ceftobiprole 500 mg should be administered as an IV infusion over 2 h every 8 h (Avirpharma, 2019). Since ceftobiprole is primarily excreted via the renal system, patients with renal impairment require a dose adjustment (CrCl <50 mL/min, 500 mg administered as an IV infusion over 2 h every 12 h; CrCl <30 mL/min, 250 mg administered as an IV infusion over 2 h every 12 h) (Torres et al., 2016; Avirpharma, 2019). The most common adverse effects reported in more than 2% of patients on ceftobiprole include infusion site reactions, hypersensitivity, nausea, diarrhea, vomiting, phlebitis and hyponatremia (Avirpharma, 2019). Dysgeusia or taste disturbance has been reported due to the diacetyl product formed upon conversion of ceftobiprole medocaryl to its active form ceftobiprole (Barbour et al., 2009; Schmitt-Hoffmann et al., 2004). The ceftobiprole label has a boxed warning for serious acute hypersensitivity including anaphylaxis, which has been observed in patients receiving this antibiotic (Avirpharma, 2019). Ceftobiprole is a novel cephalosporin antibiotic with a wide range of antibacterial activity and can be used to treat adult patients with CAP or HAP, including those caused by MRSA (Torres et al., 2016).

Besivance® (besifloxacin ophthalmic suspension)

Besivance (besifloxacin) (Fig. 2), a topical fluoroquinolone antibiotic, was approved by the US FDA for use in 2009. It is available as eye drops and indicated for the treatment of bacterial conjunctivitis due to common and resistant ocular bacteria. Other fluoroquinolone antibiotics for ophthalmic use include ciprofloxacin, gatifloxacin, levofloxacin, moxifloxacin, and ofloxacin (Lexicomp, 2021).

Besifloxacin is a fourth-generation and novel 7-aminoazepanyl-8-chloro-fluoroquinolone derivative, which works as a DNA gyrase and topoisomerase IV inhibitor. Besivance is available as 0.6% ophthalmic suspension (5 mL) and administered 1 drop into affected eyes three times daily (4–12 h apart) for 7 days (Bausch, 2020). The most common adverse events reported on Besivance include headache, conjunctival erythema, blurred vision, eye irritation, eye pain, and eye pruritus (Mahvan et al., 2014). Like other fluoroquinolone antibiotics, besifloxacin exhibited potent and broad-spectrum antibacterial activity with bactericidal effect (Haas et al., 2009). Current clinical and preclinical data support that besifloxacin is an attractive and alternative therapeutic option for the treatment of ocular infections (O'Brien, 2012).

Vibativ® (telavancin)

Vibativ (telavancin) (Fig. 2), a semisynthetic derivative of vancomycin in the lipoglycopeptide antibiotic class, was approved by the US FDA for use in 2009 (Lexicomp, 2021). It is indicated for adult patients with cSSSIs due to Gram-positive pathogens such as vancomycin-susceptible *E. faecalis*, MSSA and MRSA, *S. agalactiae*, *S. anginosus* group, and *S. pyogenes*. In 2013, telavancin was FDA approved for use in adult patients with HABP/VABP due to MSSA and MRSA (Karlowsky et al., 2015; Vibativ, 2020).

Telavancin exerts its concentration-dependent bactericidal effects via multifunctional mechanisms of action (Higgins et al., 2005). The glycopeptide core binds with a high affinity to the terminal acyl-D-Ala-D-Ala chains, which prevents polymerization, cross-linking and inhibits the bacterial cell wall synthesis. Telavancin also disrupts the function of the bacterial cell membrane as it interferes with peptidoglycan synthesis via binding to lipid II in the cell membrane (Damodaran and Madhan, 2011). This membrane-targeting mechanism of action differentiates telavancin from vancomycin, which possesses a single mechanism of action (Attwood and LaPlante, 2007; Karlowsky et al., 2015). Telavancin has a hydrophobic group attached to the amine functionality in the disaccharide moiety, which is characteristic of the lipoglycopeptide class. As such, telavancin has an improved binding affinity to the D-Ala-D-Ala chains in the peptidoglycan intermediates, due to the presence of the lipophilic decylaminoethyl side chain attached to the vancosamine sugar (Saravolatz et al., 2009). In addition, this side chain can increase the compound's activity against MRSA and VRE (Hill et al., 2010). Another notable feature of telavancin is the hydrophilic phosphonomethylaminomethyl group at the 4' position, in which phosphonic acid is negatively charged and facilitates its urinary excretion and decreases its distribution in the liver and kidney (Leadbetter et al., 2004). Both the hydrophilic moiety and the long lipophilic side chain contribute to the prolonged half-life of telavancin, allowing for once-daily dosing.

Telavancin is available as 750 mg powder in single-use vials. Telavancin 10 mg/kg should be administered as an IV infusion over 60 min every 24 h for 1–2 weeks (cSSSIs) and for 1–3 weeks (HABP/VABP) (Lexicomp, 2021). For patients with renal dysfunction, the dosage of telavancin should be adjusted (CrCl 30–50 mL/min, 7.5 mg/kg every 24 h; CrCl 10–30 mL/min, 10 mg/kg every 48 h). For patients on IV unfractionated heparin sodium, telavancin is contraindicated because it falsely elevates activated partial thromboplastin time (aPTT) for up to 18 h after telavancin administration (Vibativ, 2020). The most common adverse reactions reported in >10% of patients on telavancin are metallic or soapy taste, nausea, vomiting, and foamy urine (Vibativ, 2020). Telavancin has an FDA boxed warning for increased mortality in patients with HABP/VABP (CrCl ≤50 mL/min) in comparison to vancomycin, as well as for nephrotoxicity and embryo-fetal toxicity (Vibativ, 2020). This potent lipoglycopeptide antibiotic remains an important treatment option for patients with HABP/VABP and cSSSIs as it is effective against Gram-positive pathogens, including MRSA (Chang et al., 2010).

Teflaro® (ceftaroline fosamil)

Teflaro (ceftaroline fosamil) (Fig. 2), a fifth-generation cephalosporin prodrug, was approved by the US FDA for use in 2010 (Lexicomp, 2021). It is a broad-spectrum antibiotic with activities against aerobic and anaerobic Gram-positive and Gram-negative pathogens, as well as drug-resistant pathogens (Kaushik et al., 2011). Cefaroline fosamil is indicated for use in adult and pediatric patients with ABSSSIs or CABP (Laudano, 2011), caused by MSSA and MRSA, *S. agalactiae*, *S. pyogenes*, *E. coli*, *K. oxytoca*, *K. pneumoniae*, *H. influenzae*, or *S. pneumonia* (Media-Allergan, 2020).

The zwitterionic structure of the active form ceftaroline results in poor water solubility, thus preventing its administration via the parenteral route. The prodrug, ceftaroline fosamil, contains a solubilizing phosphonoamino group on the 1,2,4-thiadiazole ring and this structural addition increases the aqueous solubility (Kaushik et al., 2011). This phosphonate group is rapidly hydrolyzed in vivo to produce the active compound, ceftaroline (Duplessis and Crum-Cianflone, 2011). Cefaroline inhibits PBP's and exerts its bactericidal effects by disrupting bacterial cell wall synthesis (Stein and Johnson, 2011). Cefaroline inhibits PBP1-4 and has high affinities for PBP2x in *S. pneumonia*, as well as PBP2a in MRSA, which differentiates it from other cephalosporin antibiotics (Stein and Johnson, 2011; Saravolatz et al., 2011). Cefaroline contains a characteristic bicyclic cephem ring system with a 3-substituted methylpyridinium-thiazolylsulfanyl motif, as well as a 7-acylated side chain containing the Z-ethoxyimino moiety. These structural features contribute to the compound's activity against MRSA, with the oxime group improving β -lactamase resistance. The 1,2,4-thiadiazole ring at position 7 aids in increasing the affinity for transpeptidases and disrupting cell wall synthesis in Gram-negative pathogens (Kaushik et al., 2011).

Cefaroline fosamil is available as 400 and 600 mg powder in single-use vials, which requires reconstitution and dilution before the IV use (Media-Allergan, 2020). In adult patients (CrCl >50 mL/min), ceftaroline fosamil 600 mg should be given every 12 h via

IV over 1 h. For those with impaired renal function ($\text{CrCl} \leq 50 \text{ mL/min}$), a dosage adjustment is required (Laudano, 2011; Media-Allergan, 2020). The dosing of pediatric patients with ABSSSI or CABP is based on ranges of weight and age. The adverse effects occurring in more than 2% of patients on ceftaroline fosamil are rash, diarrhea, and nausea (Media-Allergan, 2020). Ceftaroline fosamil has a broader antibacterial spectrum than older cephalosporin agents and serves as a useful alternative for treating patients with ABSSSIs and CABP (Saravolatz et al., 2011).

Dificid® (fidaxomicin)

Dificid (fidaxomicin) (Fig. 3), a novel and glycosylated macrolide antibiotic, was approved by the US FDA in 2011 for the treatment of adult patients with *Clostridium difficile* infections (CDI) (Lancaster and Matthews, 2012). In 2020, the indication was expanded to include pediatric patients (≥ 6 months), with a newly approved oral suspension form. The label of fidaxomicin was also updated in 2019 to change the genus name from *Clostridium* to *Clostridioides*. *Clostridioides difficile*, an anaerobic, Gram-positive, and spore-forming organism, is responsible for causing GI infections and *C. difficile*-associated diarrhea (CDAD) (Tsutsumi et al., 2014). Fidaxomicin, also known as lipiarmycin A3, clostomicin B1, or tiacumicin B, has a narrow-spectrum activity against *C. difficile*, but does not confer activity against Gram-negative pathogens (Lancaster and Matthews, 2012; Theriault et al., 1987). The 2017 *C. difficile* guidelines published by the Infectious Diseases Society of America (IDSA) and Society for Healthcare Epidemiology of America (SHEA) strongly recommend with a high quality of evidence that fidaxomicin or vancomycin be considered as a first-line treatment over metronidazole for an initial CDI episode; there is also a weak recommendation with a moderate quality of evidence for the use of fidaxomicin over vancomycin for the first recurrent CDI (McDonald et al., 2018).

Fig. 3 Chemical structures of FDA approved antibiotics from 2011 to 2015.

Fidaxomicin exerts its bactericidal effects by inhibiting the σ subunit of bacterial RNA polymerase and subsequent RNA synthesis (Crawford et al., 2012; Yu and Sun, 2013). It also has a long postantibiotic effect in *C. difficile* of 5.5–10 h (Babakhani et al., 2011). Fidaxomicin, the active parent compound, is not absorbed systemically. Once the *O*-isobutyryl ester is hydrolyzed in vivo by gastric acid or intestinal microsomal enzymes, fidaxomicin is converted to its major active metabolite OP-1118 and the parent to metabolite ratio is 1:2 in one phase 1 study (Shue et al., 2008). Notable structural features of fidaxomicin include the highly unsaturated 18-membered macrolide core, C11 substituted 4-*O*-isobutyrate-5-methyl- β -rhamnose, and C21 substituted 2-*O*-methyl-4-*O*-homodichloro-orsellinate- β -D-rhamnose (Hochlowski et al., 1987; Serra et al., 2017).

Fidaxomicin is available as 200 mg tablets and 40 mg/mL oral suspension (Merck, 2021b). Fidaxomicin should be dosed in accordance with the IDSA's 2017 *C. difficile* guidelines which recommend that fidaxomicin 200 mg be taken by adult patients or pediatric patients >12.5 kg two times daily for a duration of 10 days (McDonald et al., 2018). For pediatric patients with weight 4 kg to less than 12.5 kg, dosing is based on weight ranges and fidaxomicin suspension (40 mg/mL) is used to deliver the calculated dose twice daily for 10 days (Merck, 2021b). No adjustments are required for patients with renal or hepatic dysfunction, pediatric patients, or other treatment groups (Lancaster and Matthews, 2012). The most common adverse reactions reported in at least 4% of patients on fidaxomicin are related to the GI disorders such as nausea, vomiting, abdominal pain, and GI hemorrhage. The fidaxomicin label has been updated to include warning of acute hypersensitivity reactions such as angioedema, dyspnea, pruritus, and rash, and it should be discontinued if a patient develops severe reactions (Merck, 2021b). Fidaxomicin is a bactericidal macrolide antibiotic with narrow-spectrum anti-*difficile* activity, and despite its high cost might serve as a better, alternative first line agent for treating CDIs (Crawford et al., 2012; Louie et al., 2011; Johnson and Wilcox, 2012; Al Momani et al., 2018).

Sirturo[®] (bedaquiline)

Bedaquiline (Fig. 3), the first drug in a new diarylquinoline chemical class with narrow-spectrum antimycobacterial activity, was approved by the US FDA in 2012 under the FDA's accelerated-approval regulations (Lexicomp, 2021; Janssenlabels, 2020). Bedaquiline is currently indicated as part of combination therapy in adult, adolescent, and pediatric (≥ 5 years and weighing ≥ 15 kg) patients with pulmonary multi-drug resistant tuberculosis (MDR-TB) (Chan et al., 2013; van Heeswijk et al., 2014; Janssenlabels, 2020). At the time of approval in 2012, bedaquiline represented the first novel anti-TB treatment in over 40 years. Bedaquiline should only be used in patients who are unable to utilize regimens of four second-line drugs and pyrazinamide in accordance with World Health Organization (WHO) recommendations or if the patient has MDR-TB that is resistant to fluorquinolones (Chan et al., 2013).

Bedaquiline exerts its antimycobacterial effects by disrupting the proton transfer chain. Specifically, it inhibits mycobacterial adenosine triphosphate (ATP) synthase and subsequently depletes the energy production in *Mycobacterium tuberculosis* (Chan et al., 2013; Singh et al., 2017). In addition, bedaquiline is selective for mycobacterial ATP synthase with minimal impact on mitochondrial ATP synthase in eukaryotic cells and human ATP synthase (van Heeswijk et al., 2014). Bedaquiline is a basic and highly lipophilic anti-TB drug ($\log P = 7.71$) with a long elimination half-life of 5.5 months (Diacon et al., 2012). It is an enantiomer with two chiral centers and 1*R*, 2*S* stereochemistry, a quinoline heterocyclic motif, and side chains with tertiary alcohol and dimethylamine functionalities that are responsible for its antimycobacterial activity (Chan et al., 2013; Singh et al., 2017).

Bedaquiline, available in 20 and 100 mg tablets, is taken orally with food by directly observed therapy (DOT) (Karumbi and Garner, 2015; Janssenlabels, 2020). The recommended dosing for adult, and pediatric (body weight ≥ 30 kg), patients with MDR-TB is bedaquiline 400 mg once daily for 2 weeks, then 200 mg three times per week (minimum 48 h between doses) for 22 weeks (Janssenlabels, 2020). The recommended dosing for pediatric patients (≥ 5 years and body weight 15–30 kg) is bedaquiline 200 mg once daily for 2 weeks, then 100 mg three times per week for 22 weeks. When used in patients with mild to moderate renal or hepatic dysfunction, no dosage adjustments need to be made, however, bedaquiline should be used with caution in patients with severe renal or hepatic dysfunction (Janssenlabels, 2020). Adjustment of medication dosages as well as increased monitoring may be necessary due to the considerable risk of drug-drug interactions associated with concomitant treatments of MDR-TB and HIV (Chan et al., 2013). The most common adverse reactions reported in at least 10% of patients on bedaquiline include arthralgia, chest pain, headache, hemoptysis, and nausea (Janssenlabels, 2020). As a boxed warning, bedaquiline has also been found to prolong the QT interval, and thus ECG monitoring is recommended and it should be discontinued when QTcF interval > 500 ms, along with the increased mortality in adults (van Heeswijk et al., 2014; Janssenlabels, 2020). Given its unique and novel mechanism of action, bedaquiline provides an alternative and important treatment option for MDR-TB, when used in combination with three to four other antitubercular drugs (Chan et al., 2013; van Heeswijk et al., 2014). Notably, acquisition of cross-resistance to bedaquiline and clofazimine via the *Rv0678* mutation was previously reported (Hartkoorn et al., 2014), and recently emerged in Pakistan following the TB treatment (Chodousi et al., 2019).

Dalvance[®] (dalbavancin)

Dalvance (dalbavancin) (Fig. 3), a second generation and semisynthetic lipoglycopeptide antibiotic, was approved by the US FDA for use in 2014. Dalbavancin was synthesized from teicoplanin, a natural antibiotic fermentation product isolated from *Nonomuraea* species (Crotty et al., 2016; David et al., 2017). It is indicated for adult patients with ABSSSIs due to susceptible Gram-positive

pathogens such as vancomycin-susceptible *E. faecalis*, MSSA and MRSA, *S. agalactiae*, *S. anginosus* group, *S. dysgalactiae*, and *S. pyogenes* (Media-Allergan, 2018). Like other glycopeptide antibiotics, dalbavancin is active against Gram-positive bacteria including MRSA (Malabarba and Goldstein, 2005).

Mechanistically, dalbavancin binds to the terminal D-Ala-D-Ala motif of peptidoglycan intermediates and inhibits transpeptidation and cross-linking of peptidoglycans, and ultimately interferes with the bacterial cell wall biosynthesis (Anderson and Keating, 2008). Notable structural features include a polycyclic peptide core, an acylated tertiary dimethylamino side chain (in red, Fig. 3) with enhanced activity against staphylococci, and a long lipophilic tail (in blue, Fig. 3) to facilitate dimerization and cell membrane interaction, as well as to increase the compound's half-life 346 h (Zhanel et al., 2010; Smith et al., 2015).

Dalbavancin is administered as an IV infusion, with currently two approved regimens for a total dose of dalbavancin 1500 mg to be delivered to a patient (Lexicomp, 2021). The two-dose recommended IV regimen for adult patients includes dalbavancin 1000 mg, followed by 500 mg administered 1 week (day 8) later. The single-dose regimen is to give dalbavancin 1500 mg IV in a single infusion, which was found to be non-inferior to the two-dose regimen, and remains another option for patients (Media-Allergan, 2018; Crotty et al., 2016). All doses should be given as an IV infusion over 30 min, and both regimens offer convenience due to the prolonged half-life 14.5 days of dalbavancin (David et al., 2017). The dosage of dalbavancin does not need to be adjusted in patients with hepatic dysfunction, as well as with renal dysfunction (CrCl >30 mL/min) or on regularly scheduled hemodialysis, as dalbavancin is not removed via hemodialysis (Crotty et al., 2016; David et al., 2017). However, patients with severe renal dysfunction (CrCl <30 mL/min) and not on regularly scheduled hemodialysis require a dosage decrease to 1125 mg (Marbury et al., 2009). In clinical studies, nausea, headache, and diarrhea were the most common adverse reactions reported in >4% of patients on dalbavancin (Lexicomp, 2021). As a treatment option to vancomycin, dalbavancin is a long-acting lipoglycopeptide antibiotic, given as a single-dose or two doses for treating patients with infections, caused by resistant Gram-positive pathogens. The convenience of once weekly dosing makes it suitable for outpatient administration of dalbavancin when treating ABSSSI (Boucher et al., 2014).

Sivextro® (tedizolid phosphate)

Sivextro (tedizolid phosphate) (Fig. 3), a prodrug to be metabolized in vivo to the active compound tedizolid, was approved by the US FDA in 2014. Tedizolid is the second agent in the oxazolidinone antibiotic class with an expanded antibacterial spectrum (Crotty et al., 2016). It is indicated for the adult and pediatric patients (≥ 12 years) with ABSSSI due to susceptible Gram-positive pathogens including MRSA (Lexicomp, 2021). Tedizolid is bacteriostatic and effective against certain strains of Gram-positive pathogens including enterococci, staphylococci, and streptococci that are resistant to other antibiotics such as vancomycin, daptomycin, or linezolid. Moreover, tedizolid is active against linezolid-resistant *S. aureus* strains that possess the *cfr* MDR gene mutation and corresponding methyltransferases (Crotty et al., 2016; David et al., 2017).

Mechanistically, rapid in vivo phosphate hydrolysis of tedizolid phosphate occurs to produce the active tedizolid, which inhibits bacterial protein synthesis by binding to the 23S rRNA portion of the 50S ribosomal subunit (David et al., 2017). The hydrophilic monophosphate group improves the compound's aqueous solubility, increases the bioavailability, and masks the primary C5 alcohol functionality from the MAO interaction (Chellat et al., 2016; David et al., 2017). Compared to linezolid, tedizolid possesses a C5 hydroxymethyl instead of acylaminomethyl group and also displays a novel and lipophilic C and D ring system, consisting of heterocyclic pyridine and methyltetrazole, respectively (Chellat et al., 2016).

For patients with ABSSSIs, tedizolid phosphate 200 mg should be administered once daily for 6 days, either by the oral route or as an IV infusion over 1 h. No dosing adjustments are required for patients with hepatic or renal impairment (Merck, 2020c). The most common adverse reactions reported in at least 2% of adult patients include headache, dizziness, nausea, vomiting, and diarrhea. It should be avoided in patients with neutropenia due to the lack of adequate data on the safety and efficacy of tedizolid in this population (Merck, 2020c). Tedizolid offers potential advantages over the use of linezolid with lower occurrences of myelosuppression and neuropathy, less bacterial resistance and MAO inhibition, as well as fewer serotonergic interactions (Prokocimer et al., 2013). Tedizolid can serve as another important treatment option for patients with ABSSSIs due to resistant Gram-positive organisms (David et al., 2017).

Orbactiv® (oritavancin)

Orbactiv (oritavancin) (Fig. 3), a semisynthetic lipoglycopeptide antibiotic, was approved by the US FDA in 2014. Oritavancin, derived from chloroeremomycin, showed excellent bactericidal activity against Gram-positive bacteria (Allen and Nicas, 2003). It is indicated for use in adult patients with ABSSSIs due to Gram-positive pathogens such as vancomycin-susceptible *E. faecalis*, MSSA and MRSA, *S. agalactiae*, *S. dysgalactiae*, *S. anginosus* group, and *S. pyogenes* (Messina et al., 2015; Orbactiv, 2019).

Oritavancin had concentration-dependent bactericidal effect with a prolonged plasma half-life of 245 h, and worked via three mechanisms such as inhibition of transglycosylation and transpeptidation and disruption of membrane integrity in bacteria (David et al., 2017; Messina et al., 2015; Orbactiv, 2019). Structurally, oritavancin is a vancomycin analog with increased efficacy toward Gram-positive pathogens because of the presences of an additional aminosugar moiety and a lipophilic *p*-chlorophenylbenzyl side

chain. A notable attribute of oritavancin is the formation of dimers, resulting in an increased affinity to bind to the peptidoglycan in bacterial cell walls and potentially exerts its rapid, bactericidal effect (Crotty et al., 2016; Zhanel et al., 2012).

Oritavancin is available in single-use vials as the diphosphate salt powder that requires reconstitution and dilution before IV administration. The IV single-dose of oritavancin in adult patients with ABSSSI is 1200 mg infused over 3 h (Crotty et al., 2016; Orbactiv, 2019). Oritavancin does not require dosage adjustments with regard to age, weight, and mild to moderate hepatic or renal impairment (David et al., 2017; Messina et al., 2015). However, data regarding the need for dosage adjustments in patients with severe hepatic or renal impairment is currently unavailable. Oritavancin is not eliminated via hemodialysis (Crotty et al., 2016). The most common adverse reactions occurring in at least 3% of patients on oritavancin include headache, subcutaneous/limb abscesses, nausea, vomiting, and diarrhea. Oritavancin falsely causes an increase in aPTT levels so the use of unfractionated heparin is contraindicated for 5 days after the treatment with oritavancin (Orbactiv, 2019). Oritavancin can also increase the serum concentration of warfarin which may cause an increased risk of bleeding (Orbactiv, 2019). Unlike vancomycin, oritavancin does not require therapeutic drug monitoring and prolonged utilization of IV catheters for administration. Thus, oritavancin may serve as a safe, effective, and long-acting treatment alternative that can provide some advantages over other available antibiotics to treat patients with ABSSSIs due to Gram-positive pathogens (Messina et al., 2015).

Xtoro[®] [DSC] (finafloxacin)

Xtoro (finafloxacin) (Fig. 3), a topical fluoroquinolone antibiotic, was approved by the US FDA for the treatment of acute otitis externa (also known as swimmer's ear) in 2014. It is used topically as ear drops for the treatment of swimmer's ear due to susceptible bacteria such as *P. aeruginosa* and *S. aureus* (McKeage, 2015). Notably, finafloxacin is the newest fluoroquinolone antibiotic for otic use, following ciprofloxacin and ofloxacin (Lexicomp, 2021). Xtoro (finafloxacin) has been discontinued in the US.

Finafloxacin belongs to the fluoroquinolone antibiotic class and works as a DNA gyrase and topoisomerase IV inhibitor. Xtoro is available as 0.3% otic suspension in a 5 mL bottle and administered four drops into the affected ear twice daily for 7 days (FDA, 2014b). The most common adverse events reported on Xtoro include itching of the ear (pruritis) and nausea (Lexicomp, 2021). Finafloxacin also showed broad-spectrum in vitro and in vivo activity against various bacterial pathogens, including those under acidic and infection-relevant conditions such as UTI and *H. pylori* infections (Jabbour et al., 2020; McKeage, 2015). In addition, it shows promise as an alternative prophylaxis and treatment option for inhalational infections due to *F. tularensis* or *Y. pestis* (Barnes et al., 2021).

Zerbaxa[®] (ceftolozane/tazobactam)

Zerbaxa (ceftolozane/tazobactam) (Fig. 3) contains a new and fifth generation 3-aminopyrazolium cephalosporin, ceftolozane, and a well-known BLI, tazobactam. This second generation β -lactam/BLI combination was approved by the US FDA in 2014 (Lexicomp, 2021). Zerbaxa is indicated for the adult patients with cAIs (in combination with metronidazole), cUTIs including pyelonephritis, HABP and VABP (since 2019), due to susceptible Gram-negative (e.g., *Bacteroides fragilis*, *E. cloacae*, *E. coli*, *K. oxytoca*, *K. pneumoniae*, *Proteus mirabilis*, *P. aeruginosa*, *H. influenzae*, and *Serratia marcescens*); as well as the GI tract Gram-positive (e.g., *S. anginosus*, *S. constellatus*, and *S. salivarius*) pathogens (Merck, 2020d).

Ceftolozane is a semisynthetic, bactericidal cephalosporin antibiotic with potent antipseudomonal activity, and works as an inhibitor of bacterial cell wall biosynthesis. Specifically, ceftolozane binds to PBPs, such as PBP1b and/or PBP3 in *P. aeruginosa* and *E. coli*, and stops peptidoglycan synthesis by inhibiting the last transpeptidation step (Lexicomp, 2021). Compared to other β -lactam antibiotics (e.g., ceftazidime and imipenem), ceftolozane showed higher binding affinity for PBPs (Sorbera et al., 2014). Ceftolozane contains features that are similar to other extended-spectrum cephalosporins such as ceftriaxone and cefepime. Structurally, ceftolozane resembles ceftazidime as both agents contain the same cephem nucleus and an almost identical 7-substituted side chain except for the aminothiadiazole ring in ceftolozane vs. the aminothiazole ring in ceftazidime. In addition, the Z-oriented oxyimino functionality at the 7 position improves compound stability to β -lactamase (Sucher et al., 2015). The dimethylacetic acid (also present in ceftazidime) and aminothiadiazole moieties at position 7 enhance Gram-negative activity against *P. aeruginosa* (Zhanel et al., 2014). The bulky side chain containing a pyrazolium heterocyclic ring at position 3 provides steric hindrance, thus improving resistance to β -lactamases (e.g., AmpC enzyme often produced by *P. aeruginosa*) (Zhanel et al., 2014; van Duin and Bonomo, 2016). The substituents attached to the pyrazolium ring have been modified to significantly increase antipseudomonal activity and reduce the risk of epileptogenicity (Cluck et al., 2015). Like other β -lactam antibiotics, potential drug resistance mechanisms of ceftolozane include ESBL production, PBP target alteration, efflux pump overexpression, and outer membrane porin loss (Hong et al., 2013).

The BLI tazobactam is a β -lactam sulfone derivative with decreased affinity to PBPs and thus insignificant antibacterial activity itself (Merck, 2020d). Tazobactam functions as an irreversible inhibitor by covalently binding to β -lactamases, and prevents the enzyme hydrolysis of ceftolozane, thereby enhancing its activity against resistant ESBL-producing pathogens, along with expanding coverage to include anaerobes (e.g., *Bacteroides* spp.) (Sorbera et al., 2014; Zhanel et al., 2014). Together, ceftolozane and tazobactam work in synergy to produce bactericidal effects.

The amount of ceftolozane and tazobactam in a single-dose vial of Zerbaxa is in a fixed 2:1 ratio (ceftolozane 1 g and tazobactam 0.5 g); and the powder requires reconstitution and further dilution before IV administration (Merck, 2020d). Zerbaxa 1.5 g should

be given every 8 h as an IV infusion over 1 h for the treatment of patients ($\text{CrCl} > 50 \text{ mL/min}$) with cIAI, in conjunction with metronidazole 500 mg IV every 8 h, for 4–14 days and cUTI (7 days); the dose of Zerbaxa for the treatment of HABP and VABP (8–14 days) is 3 g (ceftolozane 2 g and tazobactam 1 g) every 8 h given over 1 h (Merck, 2020d). For patients with impaired renal function ($\text{CrCl} \leq 50 \text{ mL/min}$), lower dosage regimens for Zerbaxa should be adjusted accordingly based on the patient's estimated CrCl (van Duin and Bonomo, 2016). The most common adverse reactions reported in at least 5% of patients on Zerbaxa include diarrhea, headache, nausea, and pyrexia for cIAI or cUTI; and diarrhea, renal impairment/failure, and hepatic transaminase increase for HABP/VABP (Merck, 2020d). Zerbaxa is a new cephalosporin/BLI combination antibiotic with enhanced activity against MDR Gram-negative organisms and can provide an alternative treatment for complicated infections such as cIAIs, cUTIs or HABP/VABP (Lexicomp, 2021), as well as a potentially valid option for patients with severe infections, caused by ESBL-producing *Enterobacterales* (Bassetti et al., 2020).

Avycaz® (ceftazidime/avibactam)

Avycaz (ceftazidime/avibactam) (Fig. 3) is a combination antibiotic containing the third generation cephalosporin, ceftazidime, and a new non- β -lactam BLI, avibactam. This second generation β -lactam/BLI combination was approved by the US FDA for use in 2015 (van Duin and Bonomo, 2016). It is indicated for the treatment of cIAIs (in combination with metronidazole), cUTIs including pyelonephritis, and HABP/VABP (since 2018), in adult and/or pediatric patients > 3 months old, due to Gram-negative (e.g., *E. coli*, *K. pneumoniae*, *Proteus mirabilis*, *E. cloacae*, *K. oxytoca*, *Citrobacter freundii* complex, *P. aeruginosa*, *Serratia marcescens*, or *Haemophilus influenzae*) and the GI tract Gram-positive (e.g., *S. anginosus*, *S. constellatus*, and *S. salivarius*) pathogens (Avycaz, 2020).

Ceftazidime alone was initially approved by the US FDA in 1985 and demonstrated broad-spectrum antibacterial activity against Gram-positive cocci as well as Gram-negative bacilli, and it was the only third generation cephalosporin with activity against *P. aeruginosa* (Lagace-Wiens et al., 2014). Ceftazidime binds to PBPs and inhibits the late stage of bacterial cell wall peptidoglycan synthesis, ultimately causing bacterial cell lysis (Lexicomp, 2021). Ceftazidime displays a characteristic and bicyclic cephem scaffold (a 4-membered β -lactam fused with a 6-membered dihydrothiazine heterocycle). Similar to other third generation cephalosporins, the 2-aminothiazole ring at the seven position enhances its binding to PBP3 in Gram-negative pathogens, thereby improving resistance to β -lactamases. In addition, the unique dimethylacetic acid at the 7 position and 3-methylpyridinium motifs in ceftazidime provide its enhanced activity against *Pseudomonas* species (Lagace-Wiens et al., 2014). Ambler class C β -lactamases-, ESBLs-, and carbapenemases-producing organisms are usually resistant to ceftazidime, hence adding the need for a combination with the BLI avibactam to overcome the increasing Gram-negative organisms' resistance to cephalosporins (Lagace-Wiens et al., 2014; Zasowski et al., 2015).

The non- β -lactam BLI avibactam inhibits β -lactamases (e.g., ESBLs, AmpC expressed in *Enterobacteriaceae* and *P. aeruginosa*, and KPC and OXA-48 expressed in *K. pneumoniae*) which inactivate cephalosporins including ceftazidime (Lagace-Wiens et al., 2014; van Duin and Bonomo, 2016). Avibactam is a slowly reversible BLI and forms a covalent bond with the hydroxyl group of the serine residue in the active site, ultimately decreasing the enzyme hydrolysis inactivation of ceftazidime (Ehmann et al., 2012). Structurally, avibactam contains a rigid diazabicyclo octane scaffold, along with multiple hydrogen bonding interactions with β -lactamases (Zasowski et al., 2015). It is important to note that avibactam does not inhibit metallo- β -lactamases (Avycaz, 2020). Interestingly, avibactam has several similar structural features with ceftazidime. For example, the 2-carboxamide, 6-sulfate, 7-carbonyl groups of avibactam (Fig. 3) resembles the 7-aminoacyl, 2-carboxylate, 8-carbonyl motifs of ceftazidime, respectively (Lagace-Wiens et al., 2014).

Avycaz is available as a sterile powder in single-dose vials for injection. For the treatment of cIAI (duration 5–14 days), cUTI and HABP/VABP (duration 7–14 days) in adult patients ($\text{CrCl} > 50 \text{ mL/min}$), Avycaz 2.5 g (ceftazidime 2 g and avibactam 0.5 g) should be given by IV infusion over 2 h every 8 h (Avycaz, 2020). The dosage for pediatric patients is weight based. The dosage regimen for Avycaz should be adjusted for all adult patients ($\text{CrCl} \leq 50 \text{ mL/min}$) (van Duin and Bonomo, 2016; Avycaz, 2020). The most common adverse effects reported in at least 5% of patients on Avycaz are nausea, vomiting, and diarrhea (Avycaz, 2020). Avycaz is a combination antibiotic containing the BLI avibactam, which widens the antibacterial activity spectrum of ceftazidime, and provides a treatment option for patients with infections due to MDR Gram-negative bacteria (GNB) such as ceftazidime-resistant GNB and CRE (Zasowski et al., 2015).

Baxdela® (delafloxacin)

Baxdela (delafloxacin) (Fig. 4), a member of fluoroquinolone antibiotic class, was approved by the US FDA in 2017. Delafloxacin is indicated for the treatment of adult patients with ABSSSIs and CABP (since 2019) (Baxdela, 2021). It is a broad-spectrum, novel fluoroquinolone antibiotic with in vitro susceptibility for aerobic Gram-positive pathogens (e.g., MSSA, MRSA, *S. haemolyticus*, *S. lugdunensis*, *S. pyogenes*, *S. agalactiae*, *S. anginosus* Group, and *E. faecalis*) and Gram-negative organisms (e.g., *E. coli*, *K. pneumonia*, *E. cloacae*, *P. aeruginosa*) (Shiu et al., 2019; Markham, 2017; Baxdela, 2021). Delafloxacin was also active in vitro against anaerobes (e.g., *Clostridium perfringens* and *Bacteroides fragilis*) and atypical organisms (e.g., *Chlamydomphila pneumonia* and *Legionella pneumonia*) (Cho et al., 2018; Shiu et al., 2019).

Similar to the other fluoroquinolones, delafloxacin inhibits DNA gyrase and topoisomerase IV, which disrupt bacteria DNA topology and replication (Jorgensen et al., 2018). Delafloxacin is a bactericidal antibiotic which shows a concentration-dependent killing of Gram-positive and Gram-negative pathogens. Unlike the other fluoroquinolones, delafloxacin inhibits DNA gyrase and topoisomerase IV enzymes equally, with enhanced activity and uptake profiles because of its generally acidic nature and unionized form in acidic environment (Cho et al., 2018; Jorgensen et al., 2018; Tulkens et al., 2019). Structurally, delafloxacin contains a 4-membered hydroxyazetidine ring at the 7 position, heteroaromatic aminodifluoropyridine ring at the 1 position, and 8-chlorine atom. Delafloxacin resistances may result from target mutations in specific portions of the bacterial topoisomerase IV and DNA gyrase, porin losses and efflux pumps (Hooper and Jacoby, 2016). However, the equal potency of delafloxacin against both topoisomerase IV and DNA gyrase targets should limit its resistance development as it requires mutations in several regions of both enzymes for resistance to occur (Tulkens et al., 2019).

Baxdela is available as both an injectable lyophilized powder and oral tablet, which contains the delafloxacin meglumine salt. For adults with an estimated glomerular filtration rate (eGFR) of ≥ 30 mL/min/1.73m², the recommended dose for the treatment of ABSSSI (duration 5–14 days) and CABP (5–10 days) is delafloxacin 300 mg IV, infused over 60 min every 12 h (Baxdela, 2021). The IV therapy can be switched to oral delafloxacin 450 mg tablet every 12 h to complete the duration of treatment. When eGFR is 15–29 mL/min/1.73m², there requires a dose adjustment (200 mg every 12 h) for the IV delafloxacin. In addition, the oral tablet should be separated from metal containing agents such as antacids and multivitamins, by 2 h before or 6 h after, to avoid the

Fig. 4 Chemical structures of FDA approved antibiotics from 2016 to 2021.

formation of metal chelation complexes and maximize absorption (Baxdela, 2021). However, for patients with ESRD, delafloxacin is not recommended as the main metabolism of delafloxacin is the phase 2 glucuronidation and excreted mainly through urine (Shiu et al., 2019). The estimated mean half-life of delafloxacin after a single IV dose and multiple oral doses is 3.7 and 4.2–8.5 h, respectively (Lexicomp, 2021). The common adverse reactions reported in at least 2% of participants in clinical studies are nausea, vomiting, diarrhea, headache and elevated aminotransferases. The boxed warning of delafloxacin includes tendinitis and tendon rupture, peripheral neuropathy, CNS effects and exacerbation of myasthenia gravis (Baxdela, 2021). There is also a caution for the CDAD risk. No clinically relevant QTc prolongation was observed in a randomized delafloxacin QT study in healthy subjects (Markham, 2017; Shiu et al., 2019). Phototoxicity of delafloxacin was also not observed in clinical studies (Cho et al., 2018). Delafloxacin serves as a valuable addition to current antibiotics used for treating ABSSSI and CABP, as it has broad-spectrum antibacterial activity such as coverage for resistant organisms (e.g., MRSA, *P. aeruginosa*), and is available as IV and oral formulations for easy switch from IV to oral when needed (Tulkens et al., 2019).

Vabomere® (meropenem/vaborbactam)

Vabomere (meropenem/vaborbactam) (Fig. 4), an IV antibiotic combination of carbapenem/BLI, was approved by the US FDA in 2017 for use in adult patients with cUTIs including pyelonephritis, due to Gram-negative pathogens such as *Enterobacter cloacae* species complex, *E. coli*, and *K. pneumonia* (Vabomere, 2020). Vabomere represents the first approved combination therapy containing a carbapenem and BLI with activity against KPC β -lactamase-producing strains (Hecker et al., 2015).

Meropenem alone was initially approved by the US FDA in 1996 as a single agent therapy, and has been discontinued in the US (Lexicomp, 2021). It is a synthetic, broad-spectrum, bactericidal carbapenem antibiotic that works by binding to PBP, thereby inhibiting bacterial cell wall synthesis (Jorgensen and Rybak, 2018). Like other carbapenem antibiotics, meropenem has a characteristic carbon atom at position 4 instead of a sulfur atom as usually seen in the penicillin class, a fused bicyclic core scaffold with an unsaturated C2=C3 double bond, as well as *trans* oriented 5 α -H and 6 β -H hydrogens. The 6-substituted 1R-1-hydroxyethyl side chain provides stability against various β -lactamases. Given that meropenem is resistant to renal dehydropeptidase I (DHP-I) due to the presence of the 4-methyl group, it is not administered concurrently with a DHP-I inhibitor such as cilastatin (Jorgensen and Rybak, 2018). Meropenem also has a 3-substituted dimethylcarbamoylpyrrolidinethio side chain, which improves its activity against Gram-negative pathogens (Craig, 1997). Potential resistance mechanisms of carbapenem include β -lactamase production, PBP target alteration, efflux pump upregulation, and outer membrane porin loss (Vabomere, 2020).

The other component of Vabomere, vaborbactam, is a non- β -lactam BLI with a cyclic boronic acid motif, and serves as an inhibitor of class A serine carbapenemases with no antibacterial activity on its own (Dhillon, 2018). Specifically, vaborbactam was developed to inactivate serine β -lactamases such as KPC, with the boronate moiety forming a covalent complex with the catalytic serine side chain of β -lactamases (Hackel et al., 2018). Vabomere showed in vitro activity against β -lactamases/ESBLs-producing *Enterobacteriaceae*, however it was largely inactive against metallo- β -lactamases or carbapenemases-producing pathogens (Wenzler and Scoble, 2020; Lomovskaya et al., 2017).

Vabomere is available in single-dose vials as a dry powder (meropenem 1 g and vaborbactam 1 g), which requires reconstitution and further dilution before IV infusion. For patients with cUTI (eGFR ≥ 50 mL/min/1.73 m²), Vabomere 4 g (2 g of meropenem and 2 g of vaborbactam) is infused every 8 h over 3 h for up to 14 days (Vabomere, 2020). Renal dosage adjustments are required for patients with eGFR <50 mL/min/1.73 m². The most common adverse events reported in at least 3% of patients on Vabomere include diarrhea, headache, infusion site reactions, and phlebitis (Vabomere, 2020). Vabomere is not recommended for patients using valproate products concurrently as it can lower their serum concentrations and increase the breakthrough seizure risk. Vabomere provides an effective treatment option for patients with cUTIs caused by CRE (Dhillon, 2018).

Solosec® (secnidazole)

Solosec (secnidazole) (Fig. 4), a 5-nitroimidazole derivative, was approved by the US FDA in 2017 for the treatment of bacterial vaginosis in adult women (Lamp et al., 1999; Lexicomp, 2021). Like other nitroimidazole agents including metronidazole and tinidazole, secnidazole showed potent in vitro activity against anaerobic Gram-positive/Gram-negative organisms such as *Bacteroides* spp., *G. vaginalis*, *Prevotella* spp., *Mobiluncus* spp. and *Megasphaera*-like type I/II, as well as parasites (e.g., amoeba) and protozoa (e.g., *Trichomonas vaginalis*, *E. histolytica*) (Gillis and Wiseman, 1996; Dailymed, 2021).

Secnidazole is a prodrug and reduced in vivo by bacterial enzymes into radical anions to presumably interfere with bacterial DNA synthesis (Lexicomp, 2021). Secnidazole is a small molecule bearing a 2-hydroxypropyl side chain at the N1 position, and taken orally as a single-dose therapy with a prolonged elimination half-life 17 h (Schwebke et al., 2017). The resistance development and associated clinical impact of secnidazole in bacterial vaginosis has not been well studied (Dailymed, 2021).

Solosec is available as oral secnidazole granules which are sprinkled onto applesauce, yogurt or pudding and consumed within 30 min; the granules should not be chewed or dissolved in a liquid. The dosage for treating adult bacterial vaginosis is a single administration of secnidazole 2 g, because of its long elimination half-life (Gillis and Wiseman, 1996; Dailymed, 2021). The most common adverse effects reported in at least 2% of patients in clinical trials include nausea, vomiting, diarrhea, dysgeusia, abdominal pain, vulvovaginal candidiasis, and vulvovaginal pruritus. It is recommended to discontinue breastfeeding for 4 days

after taking secnidazole (Dailymed, 2021). Secnidazole may serve as a useful, practical single-dose adjunct or alternative to metronidazole in the treatment of bacterial vaginosis, in cases of poor patient adherence or metronidazole resistance (Ghosh et al., 2018).

Zemdri® (plazomicin)

Zemdri (plazomicin) (Fig. 4), a semisynthetic derivative of naturally occurring aminoglycoside sisomicin, belongs to the aminoglycoside antibiotic class (Armstrong and Miller, 2010). This novel, next-generation aminoglycoside antibiotic was approved by the US FDA for use in 2018 (Eljaaly et al., 2019). Plazomicin is indicated for use in adult patients with cUTIs including pyelonephritis, due to susceptible Gram-negative pathogens such as *Enterobacter cloacae*, *E. coli*, *K. pneumoniae*, and *Proteus mirabilis* (Zemdri, 2020). Compared to other aminoglycoside antibiotics, plazomicin showed excellent in vitro activity against Gram-negative *Enterobacteriaceae* (e.g., *E. coli*, *K. pneumoniae*, and *E. cloacae*) except for *Proteus mirabilis* and carbapenem-resistant isolates with 16S rRNA methylases, as well as Gram-positive cocci including MSSA and MRSA (Walkty et al., 2014; Livermore et al., 2011; Castanheira et al., 2018).

Plazomicin is a bactericidal antibiotic with concentration-dependent killing and postantibiotic effects, and works by binding to the 30S ribosomal subunit of the bacteria, leading to inhibition of protein synthesis (Shaeer et al., 2019). Notably, most aminoglycoside modifying enzymes (AMEs) such as acetyltransferases, phosphotransferases, or nucleotidyltransferases that alter the effects of other aminoglycosides (e.g., gentamicin, amikacin, or tobramycin) do not affect plazomicin (Zemdri, 2020). Structurally similar to other aminoglycosides, plazomicin also possesses chemical modifications conferring improved resistance profile against AMEs, typically produced by CRE (Thaden et al., 2017). Specifically, plazomicin lacks the 3'- and 4'-hydroxyl groups, preventing deactivation by the AMEs that inactivate amikacin, the aminoglycoside with the widest antibacterial spectrum. Other notable structural features of plazomicin include an L- γ -amino- α -hydroxybutyryl moiety conjugated with the NH₂ group at position 1 and a hydroxyethylamino group at position 6' to improve the activity against AME-producing pathogens (Shaeer et al., 2019; Abdul-Mutakabbir et al., 2019).

Zemdri is available as a sterile, clear, colorless to yellow plazomicin sulfate solution (500 mg/10 mL) that requires dilution prior to the IV infusion. For adult patients (CrCl $\geq$ 60 mL/min) with cUTI including pyelonephritis, plazomicin 15 mg/kg (dosing based on total body weight) should be infused over 30 min every 24 h for 4–7 days (Zemdri, 2020). For patients with renal impairment (CrCl < 60 mL/min), the dosage and dosing interval for plazomicin should be adjusted accordingly. Common adverse reactions reported in at least 2% of patients on plazomicin include decreased renal function, diarrhea, and hypertension (Zemdri, 2020). Plazomicin has a boxed warning for nephrotoxicity, ototoxicity, neuromuscular blockade and fetal harm, but with lower incidence than other aminoglycosides (Thaden et al., 2017; Shaeer et al., 2019; Lexicomp, 2021). Although plazomicin is active against certain MDR Gram-negative pathogens including CRE and serves as an alternative antibacterial therapy for adult patients with cUTIs, it should be only used in patients with few to no other treatment options due to limited data on its safety and efficacy (Shaeer et al., 2019).

Xerava® (eravacycline)

Xerava (eravacycline) (Fig. 4), a new and synthetic 7-fluorotetracycline, was approved by the US FDA in 2018 for use in adult patients with cAIs (Lexicomp, 2021). Eravacycline is indicated for the treatment of cAIs, caused by some anaerobic Gram-positive *Clostridium perfringens*, *E. faecalis*, *E. faecium*, *S. aureus*, and *S. anginosus* group, as well as Gram-negative *Bacteroides* species, *Citrobacter freundii*, *E. cloacae*, *E. coli*, *K. oxytoca*, *K. pneumoniae*, and *Parabacteroides distasonis* pathogens (Xerava, 2020). Eravacycline showed a broad-spectrum in vitro antibacterial activity including against MDR organisms such as CRE and CRAB, but it was inactive against *P. aeruginosa* (Zhanel et al., 2016) and not approved for the treatment of cUTIs and CRE infections because of currently limited clinical data and/or the lack of efficacy data from clinical trials (Seifert et al., 2018, 2020; Sheu et al., 2019).

Eravacycline works by binding to the 30S ribosomal subunit to inhibit bacterial protein synthesis (Zhanel et al., 2016). Structurally similar to tigecycline, eravacycline has the 7-fluorine atom and 9-pyrrolidinoacetamido motif on the D-ring, instead of the 7-dimethylamine and 9-glycylamido moieties in tigecycline, respectively (Zhanel et al., 2016). These unique substitutions in eravacycline improved its antibacterial efficacy against tetracycline resistant and MDR strains, as well as favorable resistance and PK profiles (Abdallah et al., 2015; Livermore et al., 2016).

Xerava contains eravacycline dihydrochloride salt as a lyophilized, yellow to orange powder which is administered by the IV route after reconstitution and further dilution (Xerava, 2020). For the cAI indication, eravacycline 1 mg/kg should be given over 60 min every 12 h for 4–14 days. Dosage modification is required for patients with severe hepatic impairment or on a strong CYP3A inducer medication concomitantly (Xerava, 2020). Common adverse reactions reported in at least 4% of patients on eravacycline include infusion site reactions, nausea, and vomiting. Like other tetracyclines, eravacycline may cause permanent yellow-gray-brown tooth discoloration and reversible bone growth inhibition, when used during tooth development such as the second and third trimester of pregnancy, and by children under 8 years old. Therefore, lactating women should avoid breast-feeding during the eravacycline treatment and wait until 4 days after taking the last dose (Lexicomp, 2021). Eravacycline is a novel broad-spectrum and fully synthetic tetracycline antibiotic indicated for use in patients with cAIs and may have the potential for the treatment of serious infections caused by CRE (Sheu et al., 2019).

Seysara[®] (sarecycline)

Seysara (sarecycline) (Fig. 4), a novel tetracycline antibiotic, was approved by the US FDA for use in 2018. Sarecycline is indicated for use in patients (≥ 9 years old) with inflammatory lesions of non-nodular moderate to severe acne vulgaris (Deeks, 2019). Unlike other broad-spectrum tetracyclines, sarecycline has a narrow-spectrum activity against Gram-positive anaerobic *Cutibacterium acnes* and skin organisms such as staphylococci and streptococci, but is much less active against enteric aerobic Gram-negative microorganisms and anaerobes (Zhanel et al., 2019a; Moore et al., 2019).

Sarecycline binds to the bacterial 70S ribosomal subunits, inhibits bacterial ribosome in part by directly interacting with mRNA, and subsequent blocks protein synthesis (Batool et al., 2020). Structurally, sarecycline has a unique and extended 7-methoxy(methyl)aminomethyl side chain, which plays an important role in bacterial ribosomal binding and antibiotic action, as well as overcoming common tetracycline resistance mechanisms (Zhanel et al., 2019a; Batool et al., 2020). The exact mechanism of action when used to treat acne vulgaris is currently unknown (Almirall, 2020).

Seysara, available as sarecycline 60, 100, and 150 mg tablets, is taken orally once daily with or without food; the dose for treating acne vulgaris is 60, 100, and 150 mg for the patient whose weight is 33–54, 55–84, and 85–136 kg, respectively (Almirall, 2020). Sarecycline should be avoided during pregnancy and lactation, as well as in children (< 8 years old), due to concerns of yellow-gray-brown permanent tooth discoloration and decreased bone growth. In addition, tetracyclines were reported to induce photosensitivity, so patients taking sarecycline should minimize their exposure to sunlight and tanning beds (Almirall, 2020). Also similar to other tetracyclines, antacids (i.e., those containing calcium, magnesium, aluminum), preparations containing iron, and bismuth subsalicylate can affect sarecycline's absorption, and thus should be separated and/or avoided from doses of sarecycline (Deeks, 2019). Concomitant use of sarecycline and isotretinoin should also be avoided as both agents are associated with intracranial hypertension. The most common adverse reaction reported in 3% of patients taking sarecycline is nausea (Almirall, 2020). The current use of sarecycline is limited due to the lack of efficacy and safety data beyond 12 weeks and 12 months, respectively; therefore, continued treatment for acne with sarecycline should be reconsidered if a patient does not experience improvement after 12 weeks (Almirall, 2020).

Nuzyra[®] (omadacycline)

Nuzyra (omadacycline) (Fig. 4), a novel aminomethylcycline and semisynthetic derivative of the tetracycline antibiotic class, was approved by the US FDA for use in 2018. It is indicated for the treatment of adult patients with CABP, due to MSSA, *K. pneumoniae*, *Chlamydia pneumoniae*, *S. pneumoniae*, *H. influenzae*, *H. parainfluenzae*, *Legionella pneumophila*, and *Mycoplasma pneumoniae*, as well as ABSSSI due to MSSA and MRSA, *S. lugdunensis*, *S. anginosus* group, *S. pyogenes*, *E. cloacae*, *E. faecalis*, and *K. pneumoniae* (Nuzyra, 2020). Omadacycline showed broad-spectrum in vitro antibacterial activity against Gram-positive/Gram-negative, anaerobes, as well as atypical skin and pneumonia microorganisms (Tanaka et al., 2016).

Omadacycline works by binding to the 30S ribosomal subunit to block bacterial protein synthesis (Draper et al., 2014). Structurally, omadacycline is a close analog to minocycline and tigecycline except for the only structural difference at the nine position on the D ring. Compared to previous tetracyclines, omadacycline demonstrated improved antibacterial potency and coverage. Specifically, the addition of the neopentylaminomethyl functionality to the nine position of the tetracycline scaffold led to omadacycline with activity against other tetracycline resistant strains with ribosomal protection proteins (e.g., Tet M) and active efflux pumps (e.g., Tet K and Tet L) (Tanaka et al., 2016; Honeyman et al., 2015).

Omadacycline is administered as the tosylate salt once daily by the oral or IV route, and available as 150 mg tablets of omadacycline or 100 mg of omadacycline as a lyophilized power in a single-dose vial, which requires reconstitution and dilution prior to the IV infusion (Nuzyra, 2020). Treatment of CABP or ABSSSI is initiated with loading doses (Day 1: 200 mg by IV infusion over 60 min OR 100 mg by IV infusion over 30 min twice), followed by maintenance doses (100 mg by IV infusion over 30 min once daily OR 300 mg orally once daily) for a duration of 7–14 days (Nuzyra, 2020). The treatment of ABSSSI with Nuzyra tablets only requires loading doses Days 1 and 2: 450 mg orally once daily, followed by maintenance doses 300 mg orally once daily. Omadacycline tablets should be taken with water on an empty stomach after fasting for at least 4 h, and patients should avoid eating or drinking except water for at least 2 h after taking omadacycline. Like other tetracyclines, to promote absorption, patients should not consume products containing multivalent cations (e.g., dairy products, antacids, and multivitamins) for at least 4 h after taking omadacycline; accordingly, omadacycline should not be administered via the same IV line as multivalent cation preparations (Nuzyra, 2020). Omadacycline may cause permanent tooth discoloration or reversible bone growth inhibition when used by pregnant women during the second or third trimester of pregnancy, infants, or children (≤ 8 years). Common adverse effects reported in more than 10% of patients on omadacycline include nausea and vomiting (Lexicomp, 2021). Omadacycline is a novel 9-aminomethyl tetracycline with improved tetracycline resistance mechanisms, as well as broad-spectrum activity against anaerobes and atypical pathogens. It is a well-tolerated, once daily antibiotic that can be given by IV or oral routes, and provides a valuable treatment option for patients with ABSSSI or CABP, including those caused by resistant organisms (Barber et al., 2018; Gallagher, 2019).

Aemcolo® (rifamycin SV)

Aemcolo (rifamycin SV) (Fig. 4), an oral, minimally absorbed semisynthetic antibiotic delivered to the colon, was approved by the US FDA on November 19, 2018 for the treatment of adult patients with travelers' diarrhea due to noninvasive *E. coli* (Andrei et al., 2019). Rifamycin SV represented the first antibiotic approved for this indication following rifaximin's approval in 2004.

Aemcolo was developed using an MMX technology platform and a special coating formulation rifamycin SV, allowing it to be released slowly once it reaches the infection sites (Steffen et al., 2018). It demonstrates broad-spectrum activity against Gram-positive pathogens including *C. difficile* with moderate activity against Gram-negative bacteria (Farrell et al., 2011). Similar to rifaximin, rifamycin SV binds to the β subunit of the DdRp enzyme and inhibits bacterial RNA synthesis (Floss and Yu, 2005). Chemically, rifamycin SV is a 25-membered macrocycle containing a naphthoquinonic chromophore ring system and an amide linker between an aliphatic chain and an amino group of the aromatic moiety.

Rifamycin SV is available as 194 mg delayed-release tablets, and can be taken with or without food. For adult patients with travelers' diarrhea due to noninvasive *E. coli*, rifamycin SV 388 mg should be taken orally twice-daily for 3 days (Aemcolo, 2019). The most common adverse effects reported in at least 3% of patients on rifamycin include headache and constipation (Lexicomp, 2021). The potential benefits of Aemcolo include limited side effects and/or drug-drug interactions resulting from its nonsystemic nature, as well as a targeted release profile.

Recarbrio® (imipenem/cilastatin/relebactam)

Recarbrio (imipenem/cilastatin/relebactam) (Fig. 4) was approved by the US FDA for the treatment of adults with HABP/VABP in 2019. This new carbapenem combination therapy contains a broad-coverage carbapenem imipenem, a renal dehydropeptidase inhibitor cilastatin, and a novel BLI relebactam. Currently approved indications of Recarbrio include cIAI, HABP/VABP, and cUTI, due to susceptible Gram-negative pathogens, including *A. calcoaceticus-baumannii* complex, *E. coli*, *K. aerogenes*, and *P. aeruginosa* (Merck, 2020b). Primaxin (imipenem and cilastatin) for IV injection was initially approved by the US FDA in 1985.

Mechanistically, imipenem inhibits bacterial cell wall peptidoglycan synthesis by binding to PBP and subsequently leads to bacterial cell lysis; cilastatin prevents renal metabolism of imipenem by competing with dehydropeptidase; and relebactam protects imipenem from degradation by certain serine β -lactamases and thus restores activity against imipenem-resistant bacteria (Smith et al., 2020). Structurally similar to avibactam, relebactam is a potent BLI with the diazabicyclooctane core (a bridged bicyclic urea motif), an aminoxy-sulfate moiety, and an extra piperidine ring. As a carbapenem, imipenem has a characteristic bicyclic β -lactam ring structure with a C2=C3 double bond to increase its binding activity, as well as the 3-substituted iminomethylaminoethylthio side chain. The 1R-1-hydroxyethyl side chain at the 6 position enhances the stability to β -lactamase (Smith et al., 2020). Relebactam possesses inhibitory activity against both classes A and C β -lactamases, including KPC-2 enzymes (Wong and van Duin, 2017; Lob et al., 2017). As such, adding relebactam to imipenem and cilastatin extends its bacterial spectrum to cover some imipenem-resistant *Enterobacteriaceae* and *P. aeruginosa*, but not *A. baumannii* (Mansour et al., 2021).

Recarbrio (imipenem/cilastatin/relebactam) is available in a single-dose vial as a white to light yellow sterile powder (500 mg of imipenem, 500 mg of cilastatin, and 250 mg of relebactam), and requires reconstitution and further dilution before IV infusion (Merck, 2020b). For patients ($\text{CrCl} \geq 90 \text{ mL/min}$) with HABP/VABP, cUTI, or cIAI, Recarbrio 1.25 g is infused every 6 h over 30 min for a duration of 4–14 days (Merck, 2020b). Dosage adjustments are required for patients with renal impairment ($\text{CrCl} < 90 \text{ mL/min}$). The most common adverse events reported in at least 8% of patients on Recarbrio include increased serum alanine aminotransferase and aspartate aminotransferase, diarrhea, hypokalemia, and anemia (Lexicomp, 2021). Similar to other β -lactam/BLI combination therapies, Recarbrio provides advantages and a treatment option for bacterial infections, caused by MDR Gram-negative pathogens (e.g., CRE and MDR *P. aeruginosa*) (Heo, 2021).

Pretomanid (PA-824)

Pretomanid (PA-824) (Fig. 4), an oral, narrow-spectrum, and nitroimidazole antitubercular agent, was approved by the US FDA for the treatment of adult patients with pulmonary treatment-intolerant or nonresponsive MDR-TB or extensively drug-resistant tuberculosis (XDR-TB) in 2019. Pretomanid is the generic name and given as part of an oral three-drug combination with bedaquiline and linezolid, or the BPaL (Bedaquiline/Pretomanid/Linezolid) regimen (TBAlliance, 2019).

Pretomanid is an antimycobacterial drug with the nitroimidazooxazine core. It showed potent bactericidal in vitro activity against MDR-TB, as well as in vivo efficacy in animal infection models (Stover et al., 2000; Lenaerts et al., 2005). Mechanistically, it requires bioactivation from nitro-reduction to subsequently inhibit mycolic acid and cell wall biosynthesis. Under anaerobic environments, pretomanid functions as a respiratory poison following nitric oxide release to kill nonreplicating bacteria (Lexicomp, 2021; Stover et al., 2000). Another close structural TB drug, Delamanid (delamanid, OPC-67683) with a bicyclic nitroimidazo-oxazole motif, was approved by European Medicines Agency (EMA) in 2014 as part of a combination therapy for the treatment of MDR-TB, but has not been approved in the US yet.

Pretomanid is taken with food orally 200 mg once daily, in combination with bedaquiline (400 mg orally once daily for 2 weeks, followed by 200 mg three times per week for 24 weeks) and linezolid (1200 mg orally daily) for 26 weeks (TBAlliance, 2019). The most common adverse events reported in at least 25% of patients treated with Pretomanid in combination with bedaquiline and linezolid included peripheral neuropathy, acne vulgaris, anemia, nausea, vomiting, headache, increased serum transaminases, and musculoskeletal pain (Lexicomp, 2021).

Xenleta® (lefamulin)

Xenleta (lefamulin) (Fig. 4), a member of pleuromutilin antibiotic class, was approved by the US FDA for the treatment of adult patients with CABP in 2019, which is caused by susceptible microorganisms, including *S. pneumoniae*, MSSA, *H. influenzae*, *L. pneumophila*, *M. pneumoniae*, and *C. pneumoniae* (Xenleta, 2019).

Lefamulin is a systemic semisynthetic pleuromutilin antibiotic, which can be administered via both IV and PO routes. It has a tricyclic core scaffold containing 5-, 6-, and 8-membered ring systems, along with a substituted ester side chain at the 14 position (Zhanel et al., 2021). Diterpene pleuromutilin antibiotics were first discovered in the 1950s, lefamulin is the first drug in this class for systemic treatment of bacterial infections in humans (Veve and Wagner, 2018). It works as a protein synthesis inhibitor by binding to the 23S rRNA of the bacterial 50S ribosomal subunit (Paukner and Riedl, 2017). Lefamulin showed both bactericidal and bacteriostatic property; and was active against *S. pneumoniae*, *H. influenzae*, *M. pneumoniae*, *S. aureus* and *S. pyogenes*, but inactive against Gram-negative *Enterobacteriaceae* and *P. aeruginosa* (Eraikhuemen et al., 2021).

Xenleta is available in a single-dose clear glass vial (lefamulin 150 mg in 15 mL of 0.9% NaCl solution) and requires further dilution before IV infusion, as well as 600 mg tablets (Xenleta, 2019). To treat adult patients with CABP, lefamulin IV 150 mg is infused every 12 h over 60 min for a duration of 5–7 days or lefamulin PO 600 mg is administered orally every 12 h for 5 days (Xenleta, 2019). IV dosage adjustment is required for patients with severe hepatic impairment. The most common adverse events reported in at least 2% of patients on lefamulin include diarrhea, administration site reactions, hepatic enzyme elevation, nausea, hypokalemia, insomnia, headache, and vomiting (Lexicomp, 2021). Lefamulin provides a valuable treatment option for CABP in cases of poor clinical outcome, patient intolerance, and/or antibiotic resistance from other antibacterial therapies (Zhanel et al., 2021).

Fetroja® (cefiderocol)

Fetroja (cefiderocol) (Fig. 4), an injectable cephalosporin-siderophore conjugate, was approved by the US FDA for the treatment of adult patients with cUTI in 2019. Currently approved indications of cefiderocol include cUTI and HABP/VABP (since 2020), caused by susceptible Gram-negative microorganisms, such as *A. baumannii* complex, *E. coli*, *E. cloacae* complex, *K. pneumoniae*, and *P. aeruginosa* (Shionogi, 2020). Like some other β -lactam antibacterial agents, cefiderocol was active against carbapenem-resistant and MDR Gram-negative bacilli (Zhanel et al., 2019b).

Cefiderocol is a novel cephalosporin antibiotic conjugated with a siderophore motif. Specifically, the siderophore with a catechol moiety on the three position chelates with ferric iron, facilitating the cefiderocol delivery across the outer membrane of Gram-negative bacteria using iron transport systems (Surur and Sun, 2021). Mechanistically, cefiderocol binds to PBP and inhibits bacterial cell wall peptidoglycan synthesis, resulting in bacterial cell lysis (Lexicomp, 2021). It should be noted that cefiderocol has great structural similarity with ceftolozane and ceftazidime, except for the different 3-substituted side chains. Another minor structural difference is that ceftolozane has a 5-amino-1,2,4-thiadiazole ring on the 7-substituted side chain, compared to the 2-aminothiazole ring in ceftazidime and cefiderocol.

Fetroja (cefiderocol) is available in single-dose vials as a lyophilized powder (1 g of cefiderocol) and requires reconstitution and further dilution before IV infusion. For patients with CrCl of 60–119 mL/min, cefiderocol 2 g is infused every 8 h over 3 h for a duration of 7–14 days for HABP/VABP and 5–14 days for cUTI (Shionogi, 2020). Dosage adjustments are required for patients with CrCl <60 or ≥ 120 mL/min. The most common adverse events reported in at least 3% of patients on cefiderocol include skin rash, diarrhea, constipation, and infusion site reaction (Lexicomp, 2021). In addition to treating bacterial infections, caused by susceptible Gram-negative microorganisms, cefiderocol represents the first cephalosporin antibiotic with a clinical indication for *A. baumannii* complex.

Conclusions

New antibacterial agents and therapeutic options for the treatment of problematic bacterial infections, caused by difficult-to-treat and MDR microorganisms, are urgently needed. Since 2000, thirty-six new antibiotics have been approved by the US FDA. Among them, seven antibiotics can be considered as new chemotype antibacterial classes such as oxazolidinone (linezolid and tedizolid phosphate), lipopeptide (daptomycin), the cephalosporin-siderophore conjugate antibiotic (cefiderocol), anti-difficile macrolide (fidaxomicin), and anti-tuberculosis agents diarylquinoline and nitroimidazooxazine (bedaquiline and pretomanid, respectively). The remaining approved antibiotics are largely based on new advances and chemical modifications of existing antibacterial

classes such as carbapenem, cephalosporin, nitroimidazole, fluoroquinolone, ketolide, rifamycin, tetracycline, pleuromutilin, lipoglycopeptide, and aminoglycoside. In addition, three narrow-spectrum antibiotics (anti-difficile fidaxomicin; anti-tuberculosis bedaquiline and pretomanid), three topical agents (retapamulin, besifloxacin, and finafloxacin), four β -lactam/BLI combinations, and three monoclonal antibodies were also introduced in the clinic in the last 20 years. Notably, five brand name and/or generic products (gemifloxacin, telithromycin, tinidazole, doripenem, and finafloxacin) have been discontinued from the US market. Moreover, the important attribute, physiochemical property, mechanism of action, route of administration and dosing frequency, clinical pharmacology and indications of each antibiotic were summarized and presented in this book chapter.

With estimated 700,000 people dying worldwide annually from antimicrobial resistant infections, it is very important for researchers, clinicians, and pharmacy educators and practitioners to know these newly approved antibiotics, be knowledgeable about their approved indications and appropriate uses, and understand their unique characteristics that make them effective for the treatment of drug-resistant bacterial infections. Conversely, it is also critical for clinicians and health care professionals to understand the structural features and underlying mechanisms for antibiotic resistance so that they consciously prescribe them appropriately when absolutely needed. Finally, it should be pointed out that five new antibiotics (linezolid, tedizolid phosphate, delafloxacin, omadacycline, and lefamulin) are available for both IV and PO options, as such switching from IV to PO can benefit patient compliance, potentially eliminate the need for hospitalization, as well as save significant costs from both patient and healthcare system standpoints.

Introduction

Increasing the knowledge on possible new infection control agents to be employed as pharmaceutical or nutraceutical products in both human and veterinary medicine is a matter of urgency due to the threat of microbial antibiotic resistance. In the last half century, antibiotic resistance has had a growing impact due to the persistently selective pressure from widespread use of antimicrobials in humans, but especially in farm animals and agriculture (Breithaupt, 2014). In 2001, the European Union Ministers of Health recommended a more prudent use of antimicrobial agents in human medicine with a number of specific measures aimed to containing the spread of antibiotic resistance. Despite this, every year, the rate of resistance in several bacterial species is increasing (e.g., *Staphylococcus* spp., *Enterococcus* spp., Enterobacteria, *Pseudomonas* spp. and *Acinetobacter* spp.) (World Health Organization). Multi-drug resistance (MDR) is defined as the non-susceptibility to at least one agent in three or more antimicrobial categories, giving a representative limitation in antibiotic use, especially in severe clinical contexts (Roca et al., 2015). Being, at present, therapeutic options for curing MDR bacterial infections very limited, we are assisting to an increased mortality rate in hospitalized human patients. Since antibiotic resistance is not only of medical and social relevance but a global problem considered by the World Health Organization as one of the greatest threats to human health for the next decades, searching for new antimicrobial agents is an urgent need. Therefore, finding new antimicrobial molecules will give a contribution to increase the number of available weapons and effectively counteract the increasing resistance to conventional antibiotics thus ameliorating the management of microbial infections.

Several strategies have been proposed as alternatives to conventional antibiotics to treat microbial infections and the benefits and limits of each approach are summarized in Table 1. The present chapter, although not exhaustive, is intended to explore some of the best studied antibiotic alternatives considering the state-of-the-art, the antimicrobial spectrum, the mechanisms of action, and some controversial aspects of the most common non-conventional antimicrobials. It has to be underlined that not all antibiotic alternatives rely on the killing of the target bacteria. Actually, other strategies such as prevention of biofilm formation (and hence persistence and chronic infection control) and of toxin production (therefore controlling virulence of certain strains) are also exploited by means of metal nanoparticles (Me-NP), surfactants and quorum quenchers (QQ), since both biofilm and toxin synthesis are under quorum sensing (QS) control. In this case bacteria remain alive but their pathogenic potential is neutralized.

Living organisms

Among the several strategies to counteract pathogenic bacteria, both probiotics and phages have been proposed. This is not a conventional therapy since the used devices are not molecules but living organisms. The main principle at the basis of this choice is the biological fight for survival. Actually, bacteria living in the same ecological niche set up a huge number of competition strategies and mechanisms of predation occur between phage and bacteria. This arm race render each step of the evolutionary path a true struggle for survival and for increasing fitness (Pessione, 2020).

Table 1 Targets, adverse effects for humans and problematic aspects of the considered non-conventional antimicrobial agents.

Antimicrobial	Target	Human toxicity	Problematic issues
Probiotics	B, IS	Possible microbiota perturbations	no
Phages	B	Possible microbiota perturbations, lysogeny, immunogenicity	Bacterial resistance to phage attack
AMP	B,V,F,P,IS	Possible hemolytic activity	Protease sensitivity
Bacteriocins	B, IS	Possible membrane damage, immunogenicity.	Protease sensitivity
Quorum sensing interference	B	Possible microbiota perturbations	Alteration in the relationship with phages
Essential oils	B,V, F, P	Absent	Non-transmissible resistance by membrane modification
(Bio)Surfactants	B,V,M,F, IS	Low	no
Me-NP	B, V, F	Possible systemic diffusion	Environmental distribution in the food web

B = Bacteria, V = viruses, F = fungi, P = parasites, IS = immune system.

Probiotics

Probiotics are defined as “Living organisms that when administered in adequate amounts can support health benefits to the recipient.” Although the list of beneficial microbes is expanding every day, the best recognized probiotics’ genera are *Lactobacillus* and *Bifidobacterium* and, among yeasts, *Saccharomyces*. The huge amount of data concerning the roles of probiotics in promoting human health is still growing and after two decades of in-depth investigations several aspects of their biological functions have been elucidated (nutritional support, immune modulation, control of metabolism and cancer, gut-brain axis homeostasis) (George Kerry et al., 2018). One of the first activity recognized to probiotics was their capability to prevent and cure infection. The antibacterial strategies exerted by probiotics are summarized in Fig. 1, whereas some aspects of their antagonizing action for counteracting infection are represented in Fig. 2. From one side they can colonize the gut epithelium forming a biological barrier that prevents pathogens colonization (this is why an overdose of probiotics before tropical travels can prevent travelers’ diarrhea) meanwhile they can re-colonize an “empty” ecological niche such as the gut mucosa after prolonged antibiotic therapy. A part from this competitive exclusion, probiotics also antagonize pathogens by competing for nutrients or by producing enzymes or metabolism end-products that exert limiting effect on pathogenic growth (for instance acids, ethanol or hydrogen peroxide) (Pessione, 2014). All these strategies are “unwanted” consequences of their being alive. In parallel, they can co-aggregate with pathogens and displace them from epithelia and finally produce specific weapons, namely bacteriocins, intended to kill the competitors (Cotter et al., 2013). In addition, some probiotic bacteria can decrypt antimicrobial peptides (AMP) and immune stimulating peptides from diet-derived proteins thus indirectly controlling microbial populations at the gut level (Pessione and Cirrincione, 2016). Recently, probiotic-derived compounds have been classified as post-biotics and para-biotics (Nataraj et al., 2020). Post-biotics are all the molecules that are secreted or released by probiotic bacteria into the external environment, such as bacteriocins, acids, hormones, nutraceuticals, peptides, whereas para-biotics (exopolysaccharides, moonlighting proteins) are molecules exposed on the cell surface that can induce an immune response. At this respect para-biotics can be active even if the bacterial cell is killed, providing that no denaturation events occur. However, the distinction between para-biotics and post-biotics is sometimes artificial because weakly bound compounds (i.e. EPS, moonlighting proteins and bacteriocins) can detach and be present in the cell-free supernatant. Both post-biotics and para-biotics play an essential role in counteracting infection: post-biotics such as bacteriocins and AMP will be discussed later in the Section “Organic molecules.” Para-biotics can be used to enhance the immune response, thus stimulating an endogenous defense mechanism against pathogenic organisms (not only bacteria). Therefore, several options (the use of living probiotics, killed bacteria or also surface extracts) are suitable for enhancing immune defenses thus counteracting infection by indirect way.

Fig. 1 Main antibacterial weapons set up by probiotic bacteria.

PROBIOTICS ANTAGONISTIC BEHAVIORS

Fig. 2 Probiotic antagonistic behavior at the gut level.

Bacteriophages

Bacteriophages or phages are viruses that infect and kill bacteria by injecting their nucleic acid, replicating inside the bacterial host and causing cell lysis (Fig. 3). They are the most abundant biological entity on the planet, outnumbering bacteria by a factor of 10. They can be divided into lytic and lysogenic. The former infect and kill bacteria by producing new virions, whereas the latter integrate into bacterial genome, and become lytic only when the host bacterium is exposed to stress conditions (Howard-Varona et al., 2017). Phages are considered highly specific, but recent evidence demonstrated that some of them have a broad host range (Cazares et al., 2021).

Phage therapy is the strategy of using phages to combat bacterial infections. It was pioneered by Felix de Herelle, one of the discoverers of phages in the early 19th century, who used it successfully to treat bacterial dysentery and cholera. Nevertheless, due the rise of antibiotics, phage therapy was dismissed in the western world, and only pursued in some countries of Eastern Europe such as Georgia and Poland. However, due the increased bacterial resistance to antibiotics, phage therapy is being now adopted in countries like the United States and the United Kingdom (Düzgüneş et al., 2021).

To date, there is a growing number of clinical reports demonstrating the potential of bacteriophages to control life threatening infections, as those caused by multi drug resistant bacteria such as *Acinetobacter baumannii* and *Pseudomonas aeruginosa*. Hence it is expected that in the future their utilization could be widespread worldwide (Jennes et al., 2017; Chan et al., 2018; LaVergne et al.,

Fig. 3 Phage attack to a bacterial cell.

2018). Since resistance against a single phage arises easily, ideally phage therapy should be administered with a cocktail of lytic phages. Furthermore, these phages should not carry potentially dangerous genes, such as those codifying antibiotic resistance determinants or virulence factors (Hyman, 2019). To further improve positive phage features such as their ability to kill or disperse biofilm cells (Lu and Collins, 2007; Ferriol-González and Domingo-Calap, 2020) or to limit negative characters such as lysogeny (Blasco et al., 2019), a genetic engineering approach is proposed, thus increasing the repertoire of useful bacteriophages (Chen et al., 2019).

An additional attractive feature of bacteriophages is their ability to re-sensitize multidrug resistant bacteria towards antibiotics. This phenomenon occurs when bacteria become resistant to phages by losing the phage receptor functionality or expression. Actually, these phage receptors can be part of an antibiotic efflux pump, such as the case of the OprM protein, which is an element of at least two efflux pumps MexAB-OprM and MexXY-OprM. In 2016, Chan and coworkers demonstrated that *P. aeruginosa* PAO1 colonies that turned resistant to the lytic phage OMKO1 increased their sensitivity towards tetracycline and erythromycin for which resistance is determined by the efflux systems MexXY-OprM (Chan et al., 2016). In agreement with these data, recently it was reported that the bacteriophages ΦFG02-R and ΦCO01-R that infect *Acinetobacter baumannii* promote its re-sensibilization against beta-lactams antibiotics such as ceftazidime and against quinolones such as ciprofloxacin (Gordillo Altamirano et al., 2021). In this model, the phage receptor is in the capsular EPS and bacteria become resistant to the phage, by losing the ability to synthesize a capsule. Disruptive mutations in the gene K locus that encodes enzymes that regulate the production, modification and export of capsular polysaccharides (such as the glycosyltransferases and glucose-6-phosphate isomerase enzymes) are responsible for this phenomenon (Gordillo Altamirano et al., 2021). These phage-resistant bacteria, besides being more sensitive to antibiotics, also become more sensitive towards the action of the complement system thus resulting easily removable by the phagocytes (Gordillo Altamirano et al., 2021).

Interestingly, a recent study by (Engeman et al., 2021) demonstrated the ability of a bacteriophage cocktail (5 phages, from the families myoviridae and siphoviridae) to act synergically with several antibiotics in vitro and to re-sensitize the majority of the 14 multidrug resistant clinical isolates to at least one the following antibiotics: ceftazidime, meropenem, gentamicin, or ciprofloxacin. Moreover, the combination of the phage cocktail with ceftazidime was effective to clear *P. aeruginosa* PAO1 infection from mice wounds (Engeman et al., 2021).

Taken together these evidences suggest that phages could become a promising tool for the control of bacterial infection, when administered alone or in combination with antibiotics. However, it has to be underlined that environmental factors (pH, ions) can affect the efficacy of therapeutic phages (Jończyk et al., 2011).

Nevertheless, some constraints arise since phages are not simple molecules but they are (although host-dependent) living organisms having the potential of interacting with both microbiota and immune system. Among the possible risks are worth mentioning:

1. Quantitative/qualitative alteration of the composition of gut microbiota by selection of the phage-resistant species/strains with possible loss of beneficial species and modification of the gut metabolome (Hibbing et al., 2010).
2. Mutation of phages into potentially dangerous forms or induction of toxin production in gut bacteria, since a permanent co-evolution mechanism occurs between phages and their hosts (Koskella and Brockhurst, 2014).
3. Induction of immune responses in the human host due to rapid release of both bacterial and phage proteins after lytic events (Łusiak-Szelachowska et al., 2017).
4. Change the lytic to a lysogenic phenotype altering host gene expression and the relationship of the bacterial host with the human host (Ganeshan and Hosseinioust, 2019; Pessione, 2020).

To date only few reports, often contradictory, concerning the possible risks, are available in the literature (Galtier et al., 2016; Hsu et al., 2019) and outstanding questions remain open, requiring more in-depth studies.

Organic molecules

The molecules explored for their antibacterial activity belong to almost all biochemical classes, however proteinaceous compounds and hydrophobic/amphipathic compounds have a longer history in counteracting infections.

Antimicrobial peptides (AMP)

Natural antimicrobial peptides are produced by a large variety of organisms such as animals (Hancock and Sahl, 2006), plants (Tam et al., 2015) and bacteria (Pessione and Cirincione, 2016). Microbial-derived antimicrobial peptides (AMPs) are not synthesized at ribosomal level but are rather the result of a proteolytic action carried out by bacteria on natural proteins. These are caseins (Atanasova et al., 2014) and minor milk proteins such as whey proteins like lactoferrin (Lf) (Bruni et al., 2016), albumins and globulins (Atanasova et al., 2014). AMPs can also be obtained by chemical synthesis (Dijkshoorn et al., 2004) as well as by an abiotic action on food proteins by exploiting proteolytic enzymes generally covalently immobilized on solid surfaces and removing them after catalysis (Bellamy et al., 1992). Considering that for efficient large-scale production of antimicrobials the raw materials should be abundant and cheap, exploiting the bacterial proteolytic activity on whey proteins is the winning approach. Actually, milk

whey is a low-cost by-product of dairy industries and a huge number of microorganisms are able to grow on it (Mazzoli et al., 2014). Among them, Lactic Acid Bacteria (LAB) are the most promising since, being unable to synthesize essential amino acids, they possess a sophisticated proteolytic system allowing them to decrypt interesting peptides that are in part up-taken by the cell in part left extracellularly (Pessione, 2012).

Lactoferrin-derived peptides

Among the milk-derived antimicrobial agents, the lactoferrin-derived peptides are the most relevant. Their mode and spectrum of action together with their possible applications in the food industry, veterinary and human medicine, have been extensively reviewed in a previous paper (Bruni et al., 2016). On the other hand, the whey protein lactoferrin itself (Lf: an 80 kDa iron-binding glycoprotein) plays significant role in innate immunity. It is an important host defense molecule providing antiviral (Bojsen et al., 2007; Berlutti et al., 2011), antibacterial (Embleton et al., 2013) antifungal, anti-parasitic (Leboffe et al., 2009), immunomodulatory (Siqueiros-Cendón et al., 2014) and antioxidant activities (Kanwar et al., 2015). The most interesting antimicrobial molecules derived from proteolytic cleavage of bovine Lf are lactoferricin (Lfc) (Kitts and Weiler, 2005) and lactoferrampin (Lfa) (Van Der Kraan et al., 2005).

Lactoferricin (Lfc) is a cationic peptide resulting from pepsin digestion on Lf. Its peptide sequence (FKCRRWQWRMKKLGAPSITCVRRAF) corresponds to the fragment 17–41 of Lf. Because of its cationic charge, Lfc interacts with the negatively charged membranes, thus acting as proton gradient altering compound, perturbing permeability with consequent membrane depolarization causing direct cell death for failure of ATP synthesis (Fitzgerald and Murray, 2006). Disruption of the integrity of the biological membranes with severe ultra-structural damages also occurs, causing induction of an autolytic response (Van Der Kraan et al., 2004, 2005). The membrane target render Lfc active not only towards bacteria but also towards organisms having a different cell-wall structure such as fungi. Actually, Lfc besides assessed antibacterial action, also displays antifungal (including yeasts and filamentous fungi) activity (Bruni et al., 2016). Lfc found applications in human medicine towards the entero-hemorrhagic strain of *E. coli* O157h:7 (Muro Urista et al., 2011). As far as veterinary medicine is concerned, an in vivo study demonstrated a clinical improvement of dog's otitis using therapeutic combinations of Lfc, verbascoside and glycerophosphoinositollysine (Vercelli et al., 2015).

Lactoferrampin Lfa is a cationic peptide (WKLLSKAQEKFGKNKSR) including the residues from 268 to 284 of the N1 domain of Lf. Besides displaying cationic nature it also contains a hydrophobic domain that makes the structure amphiphilic and therefore suitable to act against Gram negatives. Lfa exhibits broad antimicrobial action against several Gram-positive genera (*Streptococcus*, *Staphylococcus*, *Bacillus*) and Gram-negative bacteria (*E. coli*, *P. aeruginosa*), yeasts (*Candida albicans*) (Van Der Kraan et al., 2005) and parasites (*Leishmania donovani*) (Théolier et al., 2014). However, due to their different amino acid composition, Lfc and Lfa can have a synergistic effect against multiresistant *S. aureus* strains, especially when combined with penicillins as suggested in (Flores-Villaseñor et al., 2010).

Casein-derived peptides

Other AMP derived from cow's milk caseins and worth mentioning are Isracidin, Casocidin-I, K-Casedicin and Kappacin.

Isracidin and Casocidin-I. These peptides, derived from alpha casein (alpha s1 and alpha s2 respectively) hydrolysis (Pessione and Cirincione, 2016), exhibit different spectrum of action: while Isracidin is active only on Gram positives, especially *S. aureus* (McCann et al., 2006), Casocidin-I also inhibits *E. coli* (Zucht et al., 1995). According to (Minervini et al., 2003) this probably occurs because of its more hydrophobic nature that can render it best fitting in passing across the Gram-negative outer membrane.

K-Casedicin and Kappacin. Both peptides originate from K-casein hydrolysis. The former is able to control *S. aureus* growth (Atanasova et al., 2014), whereas the latter is highly active towards *Streptococcus mutans* (Malkoski et al., 2001) thus representing a promising tool to treat oral infections.

Challenges and limits of AMP

Finding new strains able to decrypt AMP is a good challenge. A very recent report describes that food isolated strains belonging to *L. lactis*, *L. helveticus* and *L. rhamnosus* species are able to decrypt peptides having 100% sequence identity to well-known antimicrobial peptides reported in the data banks (Nebbia et al., 2021). Among them, K-Casedicin (*L. rhamnosus* 17D10) and the peptide LEQLRLKKY (*L. lactis* MG1363) active towards *E. coli* NEB 5 and *B. subtilis* ATCC 6051, as well as the peptide QKAL-NEINQF (*L. helveticus* 4D5) active against *S. aureus*, *L. monocytogenes*, *Bacillus cereus* and *Helicobacter pylori*. An alternative approach is the use of bioinformatic tools that can be exploited to find suitable proteins in food and related hydrolytic enzymes to perform targeted proteolysis to obtain the AMP of interest (Dziuba and Dziuba, 2014). Some limitations exist that can be highlighted by in silico studies. As an example, characterizing peptides according to their length, amino acid sequence, charge, hydrophobic residues and secondary structure (when present) can allow to establish the target (for instance Gram-positive or Gram-negative bacteria, fungi, parasites, viruses etc.) and also to reveal possible risk of failure. An interesting report by Malanovic and Lohner (2016) provides evidence that some AMP can be entrapped into anionic teichoic acids, abundant on Gram-positive bacteria, thus resulting ineffective at the membrane level where they usually act.

Recombinant cell systems or also chemical synthesis can both represent a valuable approach to obtain AMPs selective for microorganisms, but safe for human cells. These strategies include the targeted design of post translationally modified AMPs (phosphorylation, glycosylation, methylation and amidation being the main PTMs) but also insertion in the sequence of non-natural amino acids. As an example, incorporating D-amino acids into the primary sequence can alter the helical structure thus decreasing the hemolytic effect without affecting the antimicrobial potential of the AMP (Papo et al., 2002). Furthermore, these

peptides are more resistant to proteolytic cleavage (Bahar and Ren, 2013). Cationic hexapeptides, containing unusual or D-amino acids and whose critical residues are the 2nd and the 3rd amino acid, have also been constructed that proved to be active also against multi-resistant bacteria like methicillin resistant *Staphylococcus aureus* (MRSA) and *E. coli*, as well as the pathogenic fungus *Candida albicans* (Yousefinejad et al., 2015). Most of these peptides display stability in blood, therefore, they can be considered promising molecules to control infection. Interestingly, some whey proteins/peptides can have antiviral activity as suggested by Bojsen et al. (2007). In particular, a peptide from donkey milk exhibiting anti-Rotavirus efficacy has been described by Civra et al. (2015). This opens interesting perspectives also for the treatment of viral infections.

Bacteriocins

The antimicrobial activity of bacteriocins was first reported in England, in 1928 by Rogers and Whittier, who discovered that certain *Lactococcus* strains had an inhibitory effect on the growth of other LAB (Ross et al., 2002). Preliminary investigations of the antimicrobial spectrum of the newly discovered bacteriocins produced by LAB included some foodborne pathogens. Therefore, bacteriocins have been proposed for food use to prevent the growth of spoilage bacteria and foodborne pathogens, gradually acquiring a relevant role as food preservatives. They were first used in food in 1951 and the term “bacteriocin” was coined in 1953 to define colicin produced by *Escherichia coli* (Ross et al., 2002). Nisin, the best known bacteriocin produced by *Lactococcus lactis*, was discovered in parallel to penicillin and it has been applied in the food industry as a preservation agent (Delves-Broughton et al., 1996). In 1988, the FDA had approved its use as a biopreservative for a narrow range of foods and was also added to the European food additive list where it was assigned the number E234 (Ross et al., 2002). However, based on initial observations that bacteriocins may sometimes be active against clinical pathogens, studies started to appear, in which the activity of bacteriocins was tested against a more general repertoire of bacteria irrespective of their relevance with the food environment (Montalbán-Lopez et al., 2011).

It is thought that nearly 99% of all bacteria may produce at least one bacteriocin (Klaenhammer, 1988) that plays a defensive role and acts to prevent the invasion of other strains or species into an occupied niche or limit the advance of neighboring cells. An additional role has been proposed for Gram-positive bacteriocins, in which they mediate quorum sensing (Kleerebezem, 2004). Secondly, at least in *L. plantarum*, they can behave as immune modulating agents altering cytokine profiles of both monocytes (Van Hemert et al., 2010) and dendritic cells (Meijerink et al., 2010).

Bacteriocins are a heterogeneous group of anti-bacterial peptides or small proteins that vary in molecular weight, biochemical properties, spectrum of activity and mode of action, with bactericidal or bacteriostatic effect (Ross et al., 2002). Their production is under quorum-sensing control and generally modulated by bacterial stress (Mazzoli et al., 2014).

These peptides differ from antibiotics since: (i) they are ribosomally synthesized (ii) they are usually active even at very low concentrations (i.e. at the nanomolar range) (iii) they have a relatively narrow killing spectrum. Although they are generally active on bacteria closely related to the producing strain, there are evidences of relatively broad spectrum bacteriocins such as nisin and lactacin 3147 (Papadimitriou and Alexandraki, 2014).

Classification

Due to the fact that in every ecosystem bacteria produce interfering molecules to antagonize competitors, bacteriocins constitute a still underexplored and underexploited area of research to find antibiotic substitutes. The continuous discovery of new bacteriocins makes it necessary to frequently revise the proposed classification schemes. Bacteriocins can be arbitrarily divided into five groups (Fig. 4) on the basis of their biochemical structure, molecular mass, thermal stability, presence of post-translationally modified amino acids and mode of action (Cleveland et al., 2001). Each bacteriocin has the name of the producing specie/genus (colicins from *E. coli*, enterocins from *Enterococcus*, lactacins from *Lactococcus*, helveticin from *L. helveticus* etc.). Generally, lactic acid bacteria (LAB) are largely explored as producers of numerous bacteriocins since they have the advantage of being safe for use (Rea et al., 2011b).

Besides these proteinaceous compounds some bacteria can also produce small molecules having antimicrobial action. A paradigmatic example is *L. reuteri* that synthesizes three different compounds: reuterin, reuterocyclin and reuterin (Nebbia et al., 2021). While Reuterin is a proteinaceous bacteriocin-like antimicrobial (MW 2.7KDa) (Toba et al., 1991), Reuterocyclin is a small (MW 349Da) hydrophobic compound especially active towards Gram positive bacteria (Ganzle et al., 2000) whereas Reuterin is a 3-hydroxypropionaldehyde (MW 58Da) which exerts its antimicrobial activity both by inducing oxidative stress in the target cells (Schaefer et al., 2010) and by conversion into the toxic compound acrolein (Engels et al., 2016) thus displaying a broad spectrum of activity and poor selectivity (bacteria, fungi and viruses).

Mechanism of action

The best-known mechanism of action of bacteriocins is the creation of pores on the bacterial cytoplasmic membrane that results in the loss of essential macromolecules and the dissipation of the proton motive force (Moll et al., 1999). The dissipation of the gradient is achieved by Lactococcin A and other Pediocin-like bacteriocins of class II by binding to the mannose phosphotransferase system (man-PTS) (Diep et al., 2007), whereas carnocyclin A, enterocin AS-48, gasserin A and subtilisin A act independently from any binding to specific cell sites (Nishie et al., 2012). Other mechanisms include cell wall lysis (bacteriolysins) and inhibition of cell wall synthesis (mursacidin) mediated by bacteriocin binding to lipid II (Brotz et al., 1998). Nisin combines different mechanisms by acting in three sequential steps: (i) binding to lipid II, (ii) pore formation on the bacterial cytoplasmic membrane and (iii) inhibition of cell wall synthesis by removing lipid II from the cell division site (Wiedemann et al., 2006).

BACTERIOCINES CLASSIFICATION

class I	type A type B	LANTIBIOTICS
class II	type A type B type C	PEPTIDES WITHOUT MODIFIED AMINO ACIDS
class III		BATTERIOLYSINS
class IV		GLYCOPROTEINS AND LIPOPROTEINS
class V		CYCLIC BACTERIOCINS

Fig. 4 One possible classifications for bacteriocins.

Spectrum of activity

In recent years, bacteriocins have attracted much attention as antibiotic substitutes to combat infections difficult to treat with conventional antimicrobial agents (Shin et al., 2016, Mazzoli et al., 2014). In general, bacteriocins display a narrow spectrum of action: Gram-positive derived bacteriocins are more effective towards Gram-positive bacteria, whereas Gram-negative synthesized molecules preferentially act against Gram-negative pathogens. However, exceptions exist and these mainly concern Lactic Acid Bacteria (LAB) derived molecules that proved to be active also towards Gram negatives.

Bacteriocins active against Gram-positives. Pediocin-like peptides produced by LAB proved to be effective anti-listerial agents (Birri et al., 2010). Enterocin 96 and hiracin JM79 display anti-staphylococcal properties, whereas salivaricin D and subtilosin A, are efficient anti-streptococcal compounds including *S. pneumoniae* as target (Hammami et al., 2012). Nisin and lactacin 3147 are especially fitting towards Clostridia. The latter is effective against *C. difficile*, while nisin is highly performant towards both *C. difficile* and *C. perfringens* (Rea et al., 2011a). In particular, the efficacy towards *C. perfringens* also includes spores and the MICs related to *C. difficile* are very low if compared to those relative to antibiotics such as vancomycin (Udompijitkul et al., 2012). Ruminococcin A, produced by *Ruminococcus gnavus* E1 is active also against *C. botulinum*, *C. bifermentans*, *C. septicum*, *C. sordellii* and *C. sporogenes* (Dabard et al., 2001). Thuricin DC from *Bacillus thuringiensis* DPC 6431 besides killing *C. difficile* and *C. perfringens* is effective against *C. histolyticum* and *C. tyrobutyricum* (Rea et al., 2010). These anti-clostridial agents are very interesting since they can found application in food to prevent food-related infections (*C. botulinum*, *C. tyrobutyricum*, *C. perfringens*) but they can also be used to treat nosocomial events such as pseudomembranous colitis due to prolonged antibiotic therapy selecting toxin-producing *C. difficile*, which causes a severe inflammatory reaction. At this purpose, lactacin 3147 proved to be an excellent inhibitory molecule for different *C. difficile* strains especially when added in a model fecal environment (106 cells mL⁻¹ killed in 20 min) (Papadimitriou, 2014).

Bacteriocins active against Gram-negatives. *Escherichia coli* strain H22 synthesizes three bacteriocins, named colicin E1, colicin Ib and microcin C7, which are effective towards *Enterobacter*, *Escherichia*, *Klebsiella*, *Morganella*, *Salmonella*, *Shigella* and *Yersinia* (Cursino et al., 2006). Microcin J25 produced by *E. coli* is active against *Salmonella enteritidis* and virulent *E. coli* strains (Portrait et al., 1999; Sable et al., 2000). On the other hand, bacteriocins from Gram-positive LAB strains can control *H. pylori* (De Vuyst and Leroy, 2007). *Lactobacillus plantarum*, produces several bacteriocins active against Gram-negatives, among which plantaricin MG effective towards *S. typhimurium* (Gong et al., 2010) and other bacteriocins (ST28MS and ST26MS) targeting *Pseudomonas aeruginosa*, *E. coli* and *Acinetobacter baumannii* (Todorov and Dicks, 2005). A paradigmatic example among LAB is *Enterococcus* spp., which can synthesize a huge number of antibacterial compounds. Enterocin E-760 can control several Gram-negative pathogens such as *Citrobacter freundii*, *E. coli* O157:H7, *K. pneumoniae*, *Morganella morganii*, *Proteus mirabilis*, *P. aeruginosa*, *Salmonella enterica*, *Shigella dysenteriae*, *Yersinia enterocolitica*, and different species of *Campylobacter* (Line et al., 2008). The actinobacterium *Microbispora* ATCC PTA-5024 can also target the Gram-negative cocci *Neisseria meningitidis* and *Neisseria gonorrhoeae* (Castiglione et al., 2008). Finally, bacteriocin ST15 and bacteriocin E 50-52 are active towards *A. baumannii*, (Svetoch et al., 2009) an important nosocomial pathogen characterized by intrinsic resistance to most antibiotics (Imperi et al., 2011).

Bacteriocins active against MDR strains. The most problematic resistant strains are vancomycin resistant enterococci (VRE) and methicillin resistant *Staphylococcus aureus* (MRSA). Both nisin and lactacin 3147 are effective against *Staphylococcus aureus* and enterococci, respectively (Piper et al., 2009). Among the nisin structural variants (differing by a single or more amino acids) nisin F proved to be the best fitting towards resistant strains (Piper et al., 2011). Among LAB synthesized bacteriocins, mutacins produced by *Streptococcus mutans* are effective towards MRSA, VRE (Mota-Meira et al., 2005) and also multidrug resistant bacteria (MDR) such as *S. aureus* (including vancomycin and oxacillin resistant strains). The effect seems to be bactericidal on *S. pneumoniae* but only bacteriostatic on VRE (Ghobrial et al., 2009). Besides LAB, also other bacteria can produce bacteriocins able to kill resistant strains: *Staphylococcus hominis* MBBL 2-9 displays anti-MRSA activity (Sung et al., 2010), *Bacillus pumilus* WAPB4 can kill MRSA and VRE (Aunpad and Na-Bangchang, 2007), *Bacillus halodurans* C-125, besides targeting VRE is also effective towards *Bacillus anthracis* spore outgrowth (Oman and van der Donk, 2009).

Limits and open aspects

In vivo efficacy. Bacteriocins are moderately active at the physiological neutral pH. Nevertheless, some reports describe their use in skin and mucosae, after local administration as a lotion. A nisin solution applied for 2 weeks on the infected area was used to treat staphylococcal mastitis in women with remission of the infection not observed in the placebo group (Fernández et al., 2008). Mersacidin and proved to be able to eliminate MRSA from the nasal mucosa of colonized mice after intra-nasal treatment (Kruszewska et al., 2004). Gram-negative targeted molecules are best performant: Microcin J25 proved to be active towards *Salmonella* in ex vivo whole blood, plasma and serum remaining stable in all body fluids without causing hemolytic activity (Lopez et al., 2007).

Despite these promising attempts, however, some constraints arise since oral administration of bacteriocins delivered directly in a purified or semi-purified form can be challenging (Hammami et al., 2012). One of the main limits is the proteinaceous nature of most bacteriocins that can undergo proteolytic degradation. Constant efforts have been made to improve their physico-chemical properties such as solubility, diffusion and protease resistance, to render bacteriocins more stable and performant. Recent cutting-edge researches use as model lantibiotics. Salivaricin variants with conservative modifications at the trypsin-specific cleavage sites have been obtained using biotechnological strategies and 8 out of 11 variants were resistant to trypsin digestion without losing their antibacterial activity (O'Shea et al., 2010; 2013). Similarly, nisin variants with wider spectrum of activity including both Gram-positive and Gram-negative bacteria were obtained (Field et al., 2015). A possible alternative is the administration of the bacteriocin-synthesizing strain in order to produce the bacteriocin in situ (see the Section "Probiotics").

Resistance. Bacteriocins are promising tools because of the low level of acquired resistance. For instance, nisin has been used for several decades in foods (since 1953) and very low rates of resistance phenomena (frequency of about 10^{-8}) have been described (Delves-Broughton et al., 1996; Nishie et al., 2012). Similar results (frequency of 10^{-8} to 10^{-9}) have been obtained for lactacin 3147 (Guinane et al., 2006). Laboratory experiments aimed to induce resistance only result in the generation of mutants with resistance to very low concentrations of the bacteriocin (Papadimitriou, 2014).

Toxicity and perturbing action. Being targeted especially for the cytoplasmic membrane, bacteriocins display a certain degree of activity (hydrophobic interactions) also for human cells, however, their toxicity towards eukaryotes is generally low (Mazzoli et al., 2014) although no studies have examined the immunogenicity of these peptides or proteins. A second aspect to be considered is the perturbing action of bacteriocins on human microbiota. Actually, as occurs with broad spectrum antibiotics, large spectrum bacteriocins could impact bacteria different from the target infecting agents, thus altering the balance of single species inside complex microbial communities within the human host and possibly causing dysbiosis.

Quorum sensing inhibitors to control virulence

Virulence is the ability of pathogens to produce damage to the host and its attenuation represents an alternate strategy to killing bacteria for combating infections. In this regard, there is extensive research in the inhibition of bacterial virulence. In principle, any virulence determinant could be susceptible of being inhibited, however better inhibition targets are master regulators of virulence, such as the quorum sensing systems (Allen et al., 2014; Muñoz-Cazares et al., 2018).

Quorum sensing (QS) is the ability of monitoring cell density and reprogram gene expression accordingly, for this, bacteria rely in the continuous secretion of signal molecules known as autoinducers. These compounds accumulate outside the cells, and then either diffuse inside other cells and bind cytosolic receptors or bind extracellular receptors that transduce the signal. This led to the activation of transcription of the genes encoding enzymes that synthesize the autoinducers, with a rapid amplification of the phenomenon. In parallel, activation of expression of genes controlling different phenotypes occurs, thus triggering diverse processes including production of several virulence determinants such as exoproteases, toxins, phenazines, components of the biofilm matrix, etc. (Whiteley et al., 2017).

To date the main bacterial models to study QS and their inhibitors in Gram negatives are *Vibrio* spp. and *Pseudomonas aeruginosa* whereas for Gram positives is *Staphylococcus aureus*, and several approaches to inhibit they QS systems had been proved useful to decrease the virulence factor expression in vitro and in vivo in animal infection models (Castillo-Juárez et al., 2015).

QS inhibition, also known as quorum quenching (QQ) can be achieved by interfering with any component of the system, namely (i) by blocking the autoinducer receptors hence interfering with the signal binding, or (ii) by blocking the autoinducer synthases hence decreasing signal production or (iii) by degrading the autoinducers with enzymes (Kalia, 2013; Sikdar and Elias, 2020).

The more explored approach so far is interfering with the receptors, mainly with molecules from natural sources such as brominated furanones (Hentzer et al., 2003), flavonoids (Paczkowski et al., 2017) and several other plant metabolites such as cinnamic acid (Rajkumari et al., 2018) or by synthetic compounds (Borlee et al., 2010). Nevertheless, receptor inhibitors sometimes fail to inhibit the expression of QS-dependent virulence factors of clinical strains and sometimes are extremely toxic to some of them (García-Contreras et al., 2015).

Therefore, recent experimental evidences suggest that autoinducer's degradation using enzymes (such as acylases and lactonases that disrupt the Gram-negative signaling molecules acyl homoserine lactones) is a more robust strategy. By this approach it is possible to achieve higher inhibition percentages and effectiveness towards most of the clinical strains studied so far (Guendouze et al., 2017; López-Jácome et al., 2019).

Furthermore, it is possible to complement both strategies. Actually, recent investigations suggest that the combination of receptor inhibition with enzyme degradation is a much more effective approach than the application of only one agent, since the inhibition exerted is synergic and hence high QS inhibition levels are achieved with lower concentrations of the inhibitors (Fong et al., 2018).

One of the most attractive features of QS inhibition is that, in contrast with the utilization of conventional antimicrobials, it does not affect the growth of bacteria at least in vitro upon cultivation in rich media, and hence it was hypothesized that it won't create selective pressure for the development of resistance (Allen et al., 2014). On the other hand, this notion was challenged by a theoretical work in 2010 (Defoirdt et al., 2010) and by experimental evidence in 2012. It was shown in *P. aeruginosa* that growth in adenosine (whose catabolism is tightly regulated by the master QS regulator LasR) as sole carbon source make growth strongly dependent from QS. This can exert selective pressure and the development of resistance against brominated furanones, the QS interfering molecules. The resistance is based upon efflux with the MexAB-OprM pump that also effluxes several antibiotics. Moreover, clinical isolates non previously exposed to the furanones with and active pump are highly tolerant to QS inhibition by this molecule (Maeda et al., 2012).

An additional concern with QS inhibitors is the risk to affect the composition and function of complex microbial communities since several pathogenic and non-pathogenic bacterial species rely in QS for the regulation of multiple important processes, including some aspects of metabolism (Nguyen et al., 2019; Waheed et al., 2020). As an example, at least for *Escherichia coli*, QS inhibition increases the mutation rate and promote conjugation, thus increasing bacteria chances of becoming resistant against antibiotics and perhaps even to the QS inhibitors used (Li et al., 2021).

To date, the possibility of selecting resistance mechanisms against QS inhibitors is poorly explored. Therefore, it is difficult to truly establish to what extent in physiological conditions in vivo QS inhibitors are effective, compared with antibiotics.

Interestingly, QS has also a strong connection with the expression of defensive mechanisms against bacteriophages. Since it is expected that a viral infection can spread easily causing more damage in populations with high density, bacteria have evolved several QS controlled mechanisms that counteract phage predation in high cell density populations. Among them, a decrease in the expression of some phage receptors such as membrane proteins (Høyland-Kroghsbo et al., 2013; Tan et al., 2015), a lower metabolic rate, that limits phage reproduction (Qin et al., 2017) and a higher expression of defensive mechanisms like the CRISPR-CAS system (Patterson et al., 2016) or the expression of exoproteases that inactivate phages (Hoque et al., 2016) have been described.

This relationship allowed the design of therapies combining QS inhibitors and bacteriophages (Mion et al., 2019). However, it must be considered that a potential side effect of phage therapy could be the selection of QS proficient individuals that are also those with higher virulence. Hence further studies concerning the important role of QS in bacteria/phage relationship are necessary to optimize phage and phage/QS inhibitor combination therapies (Cazares et al., 2020).

Recent evidence of this complex evolutionary relationship is the presence of anti-QS mechanisms encoded by bacteriophages which inactivate QS in order to downregulate the QS mediated anti-phage mechanisms and facilitate phage infections (Shah et al., 2021).

Hence a better understanding of the ecological relationship of bacteria and phage is needed before wide application of QQ to treat infections in the clinic (Cazares et al., 2020).

Plant essential oils

The aromatic and medicinal plants can produce volatile hydrophobic secondary metabolites as a defense against infection, which can be separated by distillation or solvent extraction. They are present in a mixture of several compounds among which major and trace components can be detected and characterized by gas-chromatography and MS (Daferera et al., 2000). They prove to be active against bacteria (Mourey and Canillac, 2002), fungi (Akgul et al., 1991), viruses (Bishop, 1995) and parasites (Pessoa et al., 2002) as well as insects. These compounds, called essential oils (EOs), can be roughly divided into i) terpene-derived and ii) aromatic molecules (Miguel et al., 2010) although a huge number of molecules including alcohols, aldehydes, ketons, ethers and esters are also present (Karpouhtsis et al., 1998).

Mechanism of action

Regarding their mechanism of action, EOs can act at different cell levels. The main target is the cytoplasmic membrane, since EOs hydrophobicity can deeply alter its structure, enhancing permeability, dissipating the proton gradient and proton motive force and finally causing loss of macromolecules. Such conditions strongly compromise several essential cellular functions. Among these, pH

can decrease at values lower than 5.5 thus inhibiting the enzyme catalysis as observed in *E. coli* and *Salmonella typhi* after treatment with mustard oil (Turgis et al., 2009). Amylases, proteases and histidine carboxylase are among the most susceptible enzymes (Thoroski, 1989).

Also toxin production is dramatically stopped, probably due to energy and/or trans-membrane transport limitations, as demonstrated in *S. aureus* after exposure to oregano EO (De Souza et al., 2010). In addition, toxin production can also be limited by interference with the QS mechanism: it has been reported that of lavender, geranium, rose, rosemary and clove EOs (but not orange EO) can act as QQ (Szabó et al., 2010). Flagellin synthesis can also be inhibited by EOs, thus bacterial motility is impaired (Rudramurthy et al., 2016).

Spectrum of action

As a rule, Gram-negative pathogens, possessing an outer membrane that limits diffusion of hydrophobic molecules, are generally more resistant to every antibiotic treatment including EOs (Burt, 2004). Actually, vetiver and sandalwood EOs are completely ineffective against Gram-negatives although possessing high efficacy towards Gram-positive bacteria (Raut and Karuppayil, 2014). However, there are examples in which EOs, although less effective against Gram-negatives than against Gram-positives, can limit the growth of *Salmonella enteritidis* of about 3 logs (as respect to the 7 logs reduction towards *S. aureus*). Furthermore, low concentrations of mint EO (<0.1%, amount able to decrease the number of viable cells of only 2 logs) fortified with glucose can also suppress the production of enterotoxin B (Tassou et al., 2000), probably acting as QQ. Examples are also reported in which the efficacy against Gram-negatives is higher than that towards Gram-positives: in *E. coli* APL 87/1 oregano and clove EOs caused evident holes at cell surface whereas in *Bacillus subtilis* APL 87/35 only light cell surface modification were observed (Rhayour et al., 2003). Similarly, using the MIC of oregano EO, no damages were detected (using TEM and flow cytometry) in *S. aureus* ATCC29213, whereas in *Pseudomonas aeruginosa* ATCC 27853 both growth and the membrane potential were completely inhibited. Again, the EOs from *Salvia* spp. and *Thuya* spp., display better inhibitory activity against *P. aeruginosa* and *K. pneumoniae*, than against *S. aureus* (Jirovetz et al., 2006). These differences are related to different membrane and cell wall composition (Bouhdid et al., 2009). Generally, clove and garlic EOs display high activity towards both Gram positive and Gram negative bacteria (Arora and Kaur, 1999). However, the spectrum of activity can in some case be broadened by adding an acetate moiety to the natural compound, as demonstrated with geranyl acetate versus geraniol (Dorman and Deans, 2000). More in general, EOs proved to be active towards different bacterial species involved in food-borne infections such as *Listeria monocytogenes*, *Bacillus cereus*, *Shigella dysenteriae*, *Salmonella typhimurium* and *Escherichia coli* O157:H7 (Burt, 2004). Inhibitory activity specifically directed towards bacteria involved in pulmonary infections (*Streptococcus pneumoniae*, *Klebsiella pneumoniae*, *Haemophilus influenzae* and *P. aeruginosa*) was observed when testing *Achillea clavennae* essential oil, camphor and eucalyptol being the main components (Skocibusic et al., 2004). In particular, the anti-mycobacterial (*Mycobacterium tuberculosis* and *Mycobacterium avium*) action of *Myrtus communis* EO was described by Zanetti et al. (2010). On the basis of these overall data, also considering their historical (Boyle, 1955) and present (Vergis et al., 2015) use as food preservatives, plant-derived EOs can be appreciable tools to be explored for treating infections caused by multidrug resistant microbial strains. Actually, some reports exist that highlight the beneficial action of EOs, especially cinnamon, lemon and lemongrass against methicillin resistant *Staphylococcus aureus* (MRSA) and *Candida* (Warnke et al., 2009) and essential oils from the Australian-grown Tulsi that proved to be active against both *P. aeruginosa* and MRSA (Yamani et al., 2016). In addition, a very interesting feature of EOs (Ginger, Melissa, Sandalwood, Eucalyptus and Tea Tree) is their antiviral activity, towards both DNA and RNA viruses like adenovirus type 3, herpes simplex virus type 1 (HSV-1) and type 2 (HSV-2), poliovirus, and coxsackie virus B1 (Schnitzler et al., 2001).

Activity assessment

Different approaches have been experimented to ascertain the antimicrobial effect of EOs in vitro and both qualitative (SEM evaluation of cell morphology alterations) and quantitative methods (MIC, viable cell counts) have been used to assess their antibacterial activity (Burt, 2004). Nevertheless, as normally occurs in antibiotic susceptibility testing, also EOs sensitivity can be affected by the culture medium composition and pH: for instance, carboxylic acids and phenolic compounds are best effective at alkaline pH when both EOs and target molecules are in the protonated form (Janssen et al., 1987).

However, EOs, being a complex mixture of different secondary metabolites should be studied separately and in combination to better elucidate their potential, their possible synergies and antagonisms. As an example the combination of rosemary and clove EOs proved to be synergic against *Candida*, antagonistic against *Aspergillus* and simply additive (identical to the treatment with both compounds used separately) towards the majority of bacteria tested (*Staphylococcus*, *Escherichia* and *Pseudomonas*) (Fu et al., 2007). Interestingly a synergistic effect was also observed combining EOs with bacteriocins (Ettayebi et al., 2000). However, according to other authors, the best antimicrobial action is achieved with the natural EOs from a single plant because trace elements can improve the efficacy by acting as potentiating agents (Mourey and Canillac, 2002). The extraction method has also been referred as crucial for preserving the antibacterial activity of the overall EOs mixture present in the plant: as an example, EOs extracted by hexane support higher antimicrobial efficacy than the steam distilled ones and should be preserved in the dark (Packiyasothy and Kyle, 2002). Furthermore, some constraints arise because the chemical composition of EOs from a certain vegetal species can be affected by the geographical origin, soil, climate and harvesting time (Angioni et al., 2006) and this can influence the antibacterial spectrum of the compounds. Therefore, the accuracy and reproducibility of the experiments intended to evaluate EOs efficacy remain uncertain.

Hence, a standardization procedure to ensure the exact composition of individual molecules in commercially available EOs, together with the high-scale production by metabolic engineering, is the essential requisite to provide effective amounts of beneficial compounds to cope with infection (Carson and Riley, 2001).

Resistance and possible host-directed toxicity

Resistance mechanisms to EOs also exist. Stress proteins such as chaperones (GroEL, DnaK, Trigger factors) protecting cell structures, but especially proteins, from denaturation, were detected by in-gel proteomics in *Salmonella* after treatment with 0.01% thymol (Di Pasqua et al., 2010). However, the main resistance mechanism is linked to fatty acid modifications that decrease fluidity of the cytoplasmic membrane in Gram-positive bacteria (Ultee et al., 2000). On the other hand, also Gram-negative pathogens proved to be resistant to EOs such as the case of *P. aeruginosa* resistant to rosemary EO (Pintore et al., 2002). Finally, in spite of the huge number of studies on EOs, no genotoxic or cytotoxic effect on humans have been described, except specific cases of allergic dermatitis (Burt, 2004).

Surfactants

Surfactants are amphipathic compounds bearing a hydrophilic and a hydrophobic moiety. They can be classified as anionic, cationic, amphoteric and non-ionic, the best performant as antimicrobials being cationic and amphoteric.

The anionic detergents SDS and alkyl-sulfonates are biologically active only at very low pH and at high concentrations, nevertheless some reports highlighted anti-*S. aureus* activity (Johnston et al., 2000) and even antiviral efficacy (Tsujimura et al., 2015) of negatively-charged surfactants. However, resistance phenomena towards anionic surfactants as LAS (linear alkylbenzene sulfonates) have been described (Maehara, 2017).

Similarly, although some effects on cell viability were observed with C10E6 and C12E6 that can be adsorbed on the cell wall or enter the cytoplasmic membrane respectively, in general non-ionic detergents display poor toxicity both towards eukaryotes and prokaryotes (Falk, 2019). Amphoteric surfactants such as Dodecyl-di(aminoethyl)-glycine, are active towards 99.5% of Gram-positive bacteria, and over 99.9%, for most Gram-negative bacteria, including *Staphylococcus aureus*, *Listeria monocytogenes*, *Escherichia coli* O157:H7 and *Salmonella typhi* (Copello et al., 2008).

The historical use of cationic surfactants like quaternary ammonium salts as disinfectant agents opens new perspectives in their possible utilization as antibiotic substitutes. The antimicrobial mechanism of quaternary ammonium compounds possessing alkyl-chains, is linked to the disturbing action they exert on cell membranes, that finally results in loss of intracellular materials, cell lysis and death. For this reason, cationic surfactants are more effective against Gram-positive bacteria that lack an outer membrane, which limits diffusion of hydrophobic compounds, as previously discussed for EOs (Falk, 2019). The antimicrobial activity of a surfactant is mainly linked to the polarity of the cationic head, the higher the hydrophobicity, the higher the antibacterial power. In agreement with this, a greater antimicrobial performance can be obtained at a lower critical micelle concentration since it is related in turn to the hydrophobicity of the head-group. Actually, the more environmentally friendly gluco-cationic surfactants, bearing a polar head, display limited activity, whereas a quinolinium surfactant showed the best antibacterial efficacy (Viscardi et al., 2000). The evolution of surfactants has been guided to obtain better antimicrobial activities and enhanced biodegradability, although these two features are often opposite: actually to hydrolyze these molecules bacteria have to be resistant to their perturbing action at the membrane level. However, the last generation cationic surfactants (polymeric quaternary ammonium compounds) are more effective than the previous ones (Gerba, 2015) and di-quaternary ammonium geminis compounds prepared from N-dodecyl-betaine and gemini surfactants from arginine both display significant antibacterial activity, especially directed towards Gram-positive strains (Shukla and Tyagi, 2006).

Biosurfactants

A special place deserves surfactants of biological origin, named bio-surfactants. The hydrophobic component is a carboxylic fatty acid of variable chain-length and the hydrophilic moiety is a sugar or a peptide. They are generally divided into glycolipids and lipopeptides. As respect to oil-derived compounds which contain hydrocarbons that are degradable only by omega-oxidizing bacteria, these molecules contain fatty acids that can undergo degradation by beta-oxidation and are therefore more eco-friendly. Besides being extensively employed in food, cosmetic and pharmaceutical applications, because of their low toxicity, some of them are excellent antimicrobials (Gautam and Tyagi, 2006). Their possible mechanisms of action are: membrane disruption, interference with QS, inhibition of swarming motility and biofilm formation, inhibition of tissue adhesion (Singh and Cameotra, 2004). As an example, surface active components from *Lactobacillus acidophilus* and *L. fermentum* can prevent biofilm formation on abiotic surfaces (Velraeds et al., 1998) and adhesion of *E. faecalis* on epithelia (Heinemann et al., 2000), respectively.

Surfactins are produced by *B. subtilis*. They are cyclic lipopeptides containing a C14 fatty acid and a short peptide containing valine, leucine or isoleucine plus aspartate and glutamate that confer the anionic properties. They are effective against bacteria (Sabate and Audisio, 2013) mycoplasmas (Vollenbroich et al., 1997a), also displaying antiviral activity specifically targeting the virus envelope such as that of Herpes (Vollenbroich et al., 1997b) and HIV (Jung et al., 2000) viruses. Some constraints arise due to the fact that these compounds, targeting the cell membrane, are not so selective towards prokaryotes. Actually they have been suggested to induce cancer cells lysis (Wu, 2017). However, the toxic concentration against bacteria and host differs. Furthermore, the damage on bacterial cells is higher because bacterial membranes harbor the respiratory chain (that in *Eukarya* is in the mitochondria), therefore, disruption of electron transport and oxidative phosphorylation are the main negative events that ultimately cause bacterial cell death, without strongly affecting host cells (Falk, 2019).

Fig. 5 Molecular structure of the bio-surfactants rhamnolipids.

Massetolides A-H are produced by *Pseudomonas* species of aquatic origin and proved to be active towards *Mycobacteria*, whereas other *Pseudomonas*-derived surfactants are effective against fungi (Gerard et al., 1997).

Rhamnolipids. Rhamnolipids are glycolipids, especially produced by *Pseudomonas* spp., displaying immune modulating and anticancer activities (Fig. 5), that also prove to be good antimicrobials being effective alone and in combination with bacteriocins (Magalhães and Nitschke, 2013). They are generally more effective towards Gram-positives because of the protective effect exerted by the outer membrane on Gram negatives. They have been investigated to control food-borne infections and they proved to be bacteriostatic on *Listeria monocytogenes* and *Bacillus cereus* where about 91% of the cultures was sensitive at pH 7. Good results were obtained on *S. aureus* only at pH 5. However, on *S. aureus* they act mainly as biofilm disruptors due to the decrease of interfacial and surface tension but also as biofilm-preventing agents (Do Valle Gomes and Nitschke, 2012). These data, together with the induction of pro-inflammatory cytokines render rhamnolipids promising agents to treat Gram positive related infections, since no resistance mechanisms against them have been described so far (Thakur et al., 2021).

Metal functionalized nanoparticles (Me-NP)

Metal toxicity

Among cutting-edge technologies explored to control infectious diseases, inorganic ions play a promising role, either alone or in conjugation with (in case coated) functionalized nanoparticles (NP). This is a very recent approach derived from a long history of heavy metals use to kill bacteria. Actually since antiquity copper and silver have been employed at the solid state to prevent infections, due to their toxicity towards microorganisms (Lemire et al., 2013). Copper has been proposed as solid antimicrobial material for bed rails to control nosocomial infections (Grass et al., 2011) and very recently to be used as polymer-linked coating in biomedical applications and healthcare facilities (Mitra et al., 2019). Silver is more effective than clorexidine to prevent dental infections by *S. mutans* (Besinis et al., 2014) whereas iron has been administered as magnetite (Fe_3O_4) in association with cephalosporins to control *Klebsiella* infection. Actually, this metal form can bypass the outer membrane through the siderophore channels therefore acting as “Trojan horse” for transferring nanocoupled antibiotics into the more protected Gram-negative bacteria (Hasanova et al., 2015).

The mechanism of action of metals and Me-NP is summarized in Fig. 6. It consists in alterations exerted at the membrane level, but also in the induction of oxidative stress and related damage to lipids, proteins and nucleic acids (Lemire et al., 2013) and alteration of signal transduction (Muzammil et al., 2018). Furthermore, minor effects concerning enzyme catalysis lie in the perturbing action at the catalytic site level where exogenous metals compete with the catalytic ones or disturb the ligand geometry: this aspect is crucial since most toxins produced by bacteria are enzymes (collagenases, gelatinase, urease etc.) (Ahmed et al., 2016a).

Copper is naturally present in the environment as elemental copper in its zero-valent state (Cu^0) and ionic copper (Cu^+ or Cu^{2+}) (Georgopoulos et al., 2001). As widely reported in the literature, the membrane polarization carried out by copper ions is the main mechanism of copper antimicrobial activity. Generally, the bacterial membrane has an electrochemical potential of 100–200 mV. Cu ions can bind the membrane by electrostatic interaction and causing a depolarization of the cell membrane which results in the rupture or leakiness of material such as cytoplasm (Mitra et al., 2019). The antimicrobial activity of Copper and/or its compounds has been tested on different Gram positive and Gram-negative bacteria such as respectively *Staphylococcus aureus* and *Escherichia coli* (Mitra et al., 2019). Furthermore Cu is active towards viruses such as influenza virus and fungi such as *Candida albicans* and *Fusarium graminearum* a plant pathogenic fungus (Brunel et al., 2013).

AHMED ET AL, 2016a (From ELSEVIER)

Fig. 6 The different mechanisms of action of metal nanoparticles. From Ahmed KBA, Raman T and Veerappan A (2016) Future prospects of antibacterial metal nanoparticles as enzyme inhibitor. *Materials Science and Engineering: C* 68, 939–947, Elsevier.

Silver, the best studied antimicrobial metal, has been traditionally used as topical agent to treat local infections. Silver is currently used on healthcare devices to inhibit bacterial colonization of several abiotic surfaces and to prevent biofilm formation (Ansari et al., 2015). It displays similar mechanism of action of Cu with the advantage to be active against several bacteria (including MRSA) at very low concentrations not effective against humans: actually reduction of eukaryotic cell viability only occurs at concentration 16 fold higher than the MIC (Chen et al., 2017).

Metal NP

Nanoscale materials have emerged as novel antimicrobial agents since the small particle dimensions result in a high surface area to volume ratio that ensures improved properties to control bacterial growth (Xia et al., 2008). Antimicrobial nanomaterials, especially several classes of antimicrobial NPs, act as carrier for antimicrobial agents and the nanoparticle shape and size also influence their internalization into bacteria cells (Makvandi et al., 2020). Metal nanoparticles such as Ag₂O and TiO₂ have been used as antimicrobial materials in the food industry (Makvandi et al., 2020).

Both silver and copper NP can be considered important antimicrobial agents because they are effective towards a wide range of microorganisms including fungi, viruses and multidrug-resistant bacteria (Ingle et al., 2014). Regarding the efficacy of Cu-NP and Ag-NP, controversial results have been obtained, in part depending upon the bacterial species considered, in part from the investigating conditions. From one side Ag-NP proved to be more effective than Cu-NP against *S. aureus* and *E. coli*, whereas *B. subtilis* proved to be more sensitive to Cu-NP (Ruparelia et al., 2008). In another study, copper seemed to have some advantages: actually, both *B. subtilis* and *E. coli* are sensitive to Ag-NP and Cu-NP, however while 70 µg/mL of Ag-NP were necessary to completely inhibit the two species, for Cu-NP 60 µg/mL were sufficient (Yoon et al., 2007). Therefore, in the following paragraphs, the two Me-NP will be treated separately.

Ag-NP. Ag-NP are the most frequently employed in several medical applications such as dentistry, cardiovascular implants, bone regeneration, tissue engineering and as a biocompatible nanomaterial for producing wound healing bandages useful to contain the growth of MDR *P. aeruginosa* and *S. aureus* isolated from post-surgical wound infections (Kasithevar et al., 2017). They have also excellent antiviral properties against HIV-1 (Makvandi et al., 2020). The multilevel mechanism of action of silver NP has been extensively reviewed (Franci et al., 2015; Le Ouay and Stellacci, 2015). Ag-NP can release a huge amount of Ag atoms (about 1000) that can be oxidized to Ag⁺ ions, the true effectors of the biological damage. More in detail the Ag⁰ core seems to be responsible for the membrane integrity disruption whereas the Ag⁺ ion can form stable molecular adducts with a large variety of group (thiols, amines, phosphates) ultimately resulting in irreversible inactivation of cellular macromolecules (Le Ouay and Stellacci, 2015). Ag-NP proved to be effective against MDR *M. tuberculosis* (Seth et al., 2011) and display synergistic activity with antibiotics. Resistant

patterns were reverted into sensitivity when Ag-NP were combined with beta-lactams (Singh et al., 2013), trimethoprim and vancomycin (Naqvi et al., 2013). A further interesting aspect of Ag-NP is their efficacy in counteracting bacterial biofilm lifestyle (Franci et al., 2015). In particular, while free silver ions account for the damage to planktonic cells, integral Ag-NP can better control biofilm (Le Ouay and Stellacci, 2015). Actually, free Ag⁺ ions by forming chemical bonds with organic groups (amines, carboxylates, thiols) present in the extracellular polymeric substance in which the bacterial cells are embedded remain entrapped and are poorly effective towards biofilm-living bacteria, while Ag-NP can easily diffuse and penetrate into the biofilm core thus releasing free silver ions, the true effectors targeting the bacterial cells (Le Ouay and Stellacci, 2015). This is an appreciated feature since biofilm embedded bacterial cells poorly respond to antibiotic therapy: they are protected from antimicrobials (and antibodies) by the extracellular polymeric substance that prevents solute diffusion, and also “persister cells” appear, which by living in a non-growing state are insensitive to the antibiotic molecules (Pessione, 2021). Both citrate-capped (Habash et al., 2014) and starch-prepared Ag-NP (Mohanty et al., 2012) are able to inhibit or disrupt the biofilm of *P. aeruginosa* one of the most problematic nosocomial pathogens causing chronic infections on both abiotic (cardiac valves, catheters, prosthesis) and biotic (lung, bladder and other epithelia) surfaces. Furthermore, evidence of the capability of low Ag-NP concentrations (50 µg/mL) to inhibit biofilm formation by methicillin resistant *S. aureus* (MRSA) has been assessed by confocal laser scanning microscopy (CLSM) (Ansari et al., 2015). Anti-Staphylococcal and anti-Pseudomonas activity of Ag-NP at clinical compatible concentrations was also demonstrated together with anti-biofilm activity, with the possibility to further reduce the Ag-NP concentration by synergistic combination with antibiotics (oxy-tetracycline, amikacin, kanamycin, and streptomycin) (Barapatre et al., 2016). An additional and interesting approach to eradicate MRSA biofilms is the use of silver-coated superparamagnetic iron oxide nanoparticles (SPION) whose magnetic core can respond to external magnetic fields thus improving the anti-biofilm performances in the absence of antibiotics (Mahmoudi and Serpooshan, 2012).

Cu-NP. Copper in a form of nanoparticles has been shown to interact with the microbial cell wall because of its affinity with the carboxyl groups present on the microbial surface (Ingle et al., 2014) and causes cell death. This phenomenon is called as “contact killing.” Zero-valent Cu-NP have been demonstrated by SEM to form micro-cavities in *E. coli* cell wall which becomes thick and coarse (Raffi et al., 2010). Interestingly Cu-NP can cause degradation of viral proteins (SDS-PAGE evaluation) such as hemagglutinin and neuraminidase finding application in very up-to-date tools such as filters and face masks (Fujimori et al., 2012). Finally, a further advantage of Cu-NP is that copper is less expensive than silver.

Controversial aspects

Some adverse effects of metals can be exerted also towards the human host and are dependent on the concentration. It is well known that physiological cations such as iron, copper, zinc and manganese that are normally present as catalysts in the active site of most enzymes can be toxic at very high doses, whereas toxic metals like silver and selenium are useful at low concentrations. NP can accumulate in the respiratory tract depending on their size, thus causing oxidative stress and inflammatory responses (Madl and Pinkerton, 2009). Systemic distribution of particles is favored by their ability to diffuse through both cellular and intercellular barriers which is partially determined by particle surface charge (Chang et al., 2012) solubility (Ameh and Sayes, 2019) and size. Small size Cu-NP can translocate and enter blood circulation accumulating in other organs (Lee et al., 2016). Unfortunately, smaller sized nanoparticles (i.e. 10 nm) displaying a better antibacterial activity (as respect to larger sized particles (100 nm)) are those exhibiting the higher risk (Padil and Cernik, 2013).

Several approaches have been proposed to reduce adverse effects of metal and metal oxide NP. Immobilization in polymeric matrices such as alginate, chitosan, polyethylene glycol (Makvandi et al., 2020), or also human serum albumin (Seth et al., 2011) can change the interaction with the mammalian cells meanwhile providing release of antimicrobials and a good hydration useful for chronic ulcers and burns re-epithelization (Makvandi et al., 2020). β-cyclodextrin is an effective capping and stabilizing agent able to decrease NP toxicity towards human cells (Jaiswal et al., 2015). Furthermore, green chemistry strategies also promote better biocompatibility: indeed, algae- (Makvandi et al., 2020) as well as plant extract- (Ahmed et al., 2016b) mediated synthesis allow to obtain metal NP with lower cytotoxicity. An interesting strategy for the synthesis of Ag-NP from AgNO₃ enzymatic reduction using lignin-degrading fungi has been proposed. The ecofriendly process allowed to obtain hexagonal-shaped Ag-NP with high efficacy towards clinical pathogens and with improved biocompatibility (Barapatre et al., 2016).

Nevertheless, environmental aspects have to be taken into account before use. Actually, environmental released NP undergo transformations such as aggregation, sedimentation, dissolution, adsorption and complexation that facilitate persistence, bioavailability and bioaccumulation in the food web (Ameh and Sayes, 2019). Although at present the trophic transfer of NP through the food chain is poorly explored (Gardea-Torresdey et al., 2014), possible induced toxicities in several living organisms like sea urchins (Torres-Duarte et al., 2016), fish (Griffitt et al., 2007) phytoplankton (Bielmyer-Fraser et al., 2014) and terrestrial plants (Hong et al., 2015; Zhao et al., 2016) have been reported. As far as gut microbiota is concerned, preliminary data highlight modifications induced by Ti-NP on some phenotypic patterns, especially growth profiles and biofilm forming attitude, of *Lactobacillus* and *Enterococcus* (personal unpublished results), however a true systemic evaluation on the gut ecosystem as a whole is very difficult to achieve and further research by using innovative approaches is needed. Due to all these possible environmental risks, understanding of the processes underlying their biological activity deserve more in depth investigations and critical considerations. However, at present, metal-NP-based antimicrobials for systemic use are far to find full application in therapy, and clinical trials are currently underway. Therefore, it can be concluded the use of metal-NP in therapy beyond to the safety limits should be carefully evaluated to avoid severe cytotoxicity.

A second aspect to be considered is the acquisition of resistance by bacterial populations. Different mechanisms of resistance to metals are known. First, the production of extracellular or intracellular compounds like proteins, the sulfur-rich metallo-thionines, having a chelating effect on cations. Second, the capability to change the redox state of the metals converting the dangerous forms (ions) into milder ones (elemental state). Third the existence of modified uptake systems (with low affinity for the toxic metal) or efflux systems for metals similar to those used to extrude antibiotics or other toxic compounds (Lemire et al., 2013). Finally, the possibility to use the metal for dissimilatory reduction pathways during anaerobic respiration also constitutes a factor of metal resistance. However, the conjugation with NP render all these mechanisms difficult to achieve, although it should be taken into account the possibility of adduct formation with environmental cations, amines and chlorides (Le Ouay and Stellacci, 2015). As far as Me-NP are concerned a peculiar resistance mechanism has been described in Gram-negative bacteria: *E. coli* with mutations in the porin channels involved in Ag-ions transport proved to be less sensitive to AgNP (Li et al., 1997).

Other antimicrobial strategies

To conclude this report, some less explored approaches should be mentioned. Additional antibacterial compounds include immunomodulators (Cheng et al., 2014) capsaicin (Marini et al., 2015) prodigiosin that induces bacterial autolysis (Danevcic et al., 2016) the biofilm inhibiting emodin from aloe (Xiang et al., 2017) and EPS. The latter have recently received increased attention both for their immune-stimulating properties, and for their direct antibacterial effect. EPSs immunomodulatory effect could be due both to their binding to toll-like receptors (TLR) on immune cells and to their prebiotic activity, promoting gut microbiota growth and diversity and, therefore, indirect immune activation (Chaisuwan et al., 2020). As far as the direct antibacterial activity is concerned, three antibacterial mechanisms have been proposed for EPS: (i) suppression of nutrients uptake and microbial growth through metal chelation, (ii) surface ionic interaction resulting in cell wall disruption, and (iii) inhibition of mRNA and protein synthesis (Tokura et al., 1997). EPSs from *Lactobacillus kefiranoferiens* DN1 showed an inhibiting activity against the growth of *Listeria monocytogenes* and *Salmonella enteritidis* (Jeong et al., 2017), while EPSs from *Lactococcus lactis* F-mou inhibited *Enterobacter cloacae*, *Escherichia coli*, *Proteus mirabilis*, *Pseudomonas aeruginosa*, *Acinetobacter baumannii*, *Bacillus cereus*, *Staphylococcus aureus*, *L. monocytogenes*, and *Candida albicans*, (Nehal et al., 2019). Finally, there is evidence of antibacterial activity against *E. coli* and *S. aureus* from *Leuconostoc pseudomesenteroides* dextran (Ye et al., 2019). Furthermore, a very recent and interesting report highlights the antibacterial potential of cannabidiol against *S. aureus* infections (Blaskovich et al., 2021).

Concluding remarks

To face the current challenge of multidrug resistance towards the main classes of antibiotics, several alternative strategies have been proposed, and most of them have been explored in this chapter. Most of the molecules described originate from the bacterial world (bacteriocins, antimicrobial peptides, biosurfactants, quorum quenchers, prodigiosines and exopolysaccharides). However, some compounds are derived from plants (e.g. essential oils) or could also be obtained by chemical synthesis (surfactants, AMP, QQ). Table 1 summarizes the main targets and adverse effects. Most benefits are linked to their activity at very low concentrations, nevertheless, some controversial aspects still arise because of the chemical nature of the proposed compounds, which cannot find application in every body district (e.g. surfactants, highly hydrophobic molecules), and because only studies over the long run can fully ascertain the absence of resistance phenomena or environmental safety.

A special mention deserves the use of phages and probiotics: these are living organisms that can deeply alter the endogenous ecological niche such as the gut micro habitat and have profound consequences on the overall health homeostasis. A promising approach is the use of compounds limiting bacterial virulence (adhesion, biofilm formation, persistence, toxin production) without killing microbial cells: in this case the effects on the ecosystems, appear to be negligible, at least for biosurfactants, since recent reports on QQ highlight selective pressure on microbial communities (Waheed et al., 2020) and altered microbial diversity (Liu et al., 2020).

Taken together, all these considerations suggest that when a choice is necessary among these alternative compounds, the same criteria used for antibiotics should be employed: good activity in the target tissue, selectivity and low toxicity towards humans, limited induction of resistance phenomena and perturbing effects on the endogenous microbiota, immune system and overall ecosystems. At the same time it is of primary importance to avoid incorrect use, if not, just few years might be necessary to lose this second opportunity.

Antimicrobial prophylaxis is used to prevent infectious diseases, the occurrence of which are associated with a threat to human health and life. This approach can be applied to the entire population or to selected social groups that are particularly susceptible to the effects of a disease. The implementation of anti-infective prophylaxis is important for an individual patient and for the entire population (Enzler et al., 2011).

Antimicrobial prophylaxis can be realized as preexposure (PrEP) in a situation where it is administered prior to potential contact with an infectious agent, or postexposure (PEP) when it is administered after exposure to an infectious agent. Various methods of therapy are used in both methods of administration (Davey et al., 2015):

- chemoprophylaxis based on the use of chemical drugs;
- immunoprophylaxis including the use of appropriate protective vaccinations;
- infusions of specific or non-specific immunoglobulins.

Antimicrobial prophylaxis may be considered primary (prevention of an initial infection) or secondary (prevention of the recurrence or reactivation of an infection), or it may be administered to prevent infection by eliminating a colonizing organism. The essence of prophylaxis is the fact that it should eliminate effectively the risk of infection, be non-toxic for the patient, not generate bacterial resistance in the population, and be low cost (Voit et al., 2005).

There are several risk factors for a particularly severe course of infection in selected groups of patients. The most frequently mentioned are: extremes of age, malnutrition and obesity, coexistent infections, immunosuppression, corticosteroid therapy, diabetes mellitus, and recent medical procedures—in hospitalized patients, the length of hospitalization and known colonization with resistant bacteria are crucial. Choosing the right prophylactic method is an important element of patient care, and each case should be considered in terms of effectiveness and the specific patient group.

Preexposure prophylaxis

Chemotherapy

PrEP chemoprophylaxis means using antibacterial or antiviral drugs in negative patients before potential exposure to infectious agent. In particular, prevention is dedicated to selected groups of high-risk patients, who include:

- HIV-infected patients;
- solid organ transplant recipients;
- hematopoietic cell transplant (HCT) recipients;
- patients before/after surgical interventions;
- health care workers.

The physician supervising patients from the above-mentioned groups should monitor the regional recommendations for prophylaxis on an ongoing basis.

Preexposure prophylaxis in HIV

For HIV-negative people who are at high risk for acquiring HIV and are committed to medication adherence, PrEP is a highly effective method of prevention. It can reduce the risk of viral transmission in more than 90% of patients (Anderson et al., 2012).

Candidates for HIV-PrEP are adults and adolescents who are at high risk of acquiring HIV. These individuals are from the following groups:

- men and women without HIV who have a sexual partner with HIV with a detectable viral load in their blood. However, PrEP can be advised to all HIV-negative individuals who have a serodiscordant partner: There is a very low likelihood of transmission if the partner with HIV has stably suppressed plasma HIV RNA and is adherent to their antiretroviral therapy (LeMessurier et al., 2018);
- men who have sex with men (MSM) and transgender women who have sex with men if, within the last 6 months, they have engaged in high-risk sexual behaviors (e.g., condomless anal sex with multiple or anonymous sex partners or a main partner with HIV risk factors) and a documented bacterial sexually transmitted infection (STI);
- heterosexually active HIV-negative men who have condomless sex with female partners from regions with generalized HIV epidemics, where the prevalence of HIV is $\geq 3\%$ according to the World Health Organization (WHO, 2016a,b) recommendations. However, the new guideline panels presented in 2018 suggest a lower prevalence, namely $\geq 2\%$ (Saag et al., 2018);
- injection drug users who have reported sharing needles/equipment (within the last 6 months), if they have initiated substance use treatment (WHO, 2016a,b);
- heterosexual men who have, in the last 6 months, been diagnosed with a bacterial STI or have engaged in condomless sex with female partners from areas of low general HIV prevalence but who are at high risk of HIV infection (e.g., sex workers, injection drug users; WHO, 2016a,b).

In the United States, HIV PrEP was approved by the Food and Drug Administration (FDA) for use in adolescent HIV-negative individuals (Gilead Sciences, 2018). The reason for this decision was the rapidly growing rate of HIV infection among young MSM in recent years.

Proposed procedure and regimen

The first medication regimen approved by FDA and recommended for PrEP for all populations is a one-dose combination of tenofovir disoproxil fumarate (TDF) 300 mg co-formulated with emtricitabine (FTC) 200 mg. Adverse reactions like mild gastrointestinal disturbances (e.g., nausea, diarrhea), which can resolve in first weeks of therapy, have been described in some clinical trials. However, the patients should be observed for potential risk of renal and bone toxicity, especially for long-term use (Centers for Disease Control and Prevention (CDC), 2017a,b).

The second option approved by FDA (2019) is also a one-pill therapy, namely tenofovir alafenamide (TAF) 25 mg co-formulated with emtricitabine 200 mg, but this combination is not recommended for adults and adolescents whose main risk is vaginal, receptive sex. The TAF-FTC combination has better renal and bone safety than TDF-FTC, but it can be associated with dyslipidemia and mild weight fluctuations (Hare et al., 2019).

Solid organ transplant recipients

Solid organ transplant recipients are a high-risk group that can develop different infections—viral, fungal, and bacterial—but their individual risk depends on the type of transplanted organ, type of immunosuppression used, and the pathogens existing in their environment (Husain et al., 2016). The most important sources of infection in solid organs transplants are:

- reactivation of latent infections carried by the solid organs transplant recipients or the organ donor. The most common pathogens that can produce reactivation are *Cytomegalovirus* (CMV), Epstein-Barr virus (EBV), herpes simplex virus (HSV), varicella-zoster virus (VZV), *Toxoplasma gondii*, *Strongyloides stercoralis*, and *Trypanosoma cruzi*. All recipients and donors should be tested before the transplantation to establish the best prevention procedure. In many countries, pre-transplant procedures are regulated by internal recommendations; therefore, doctors caring for this group of patients should be kept informed about the current recommendations;

- new colonization by pathogens typical for the hospital environment (Fishman, 2017). Colonizing organisms may include antimicrobial-resistant organisms such as methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci, carbapenem-resistant *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Aspergillus* spp., *Stenotrophomonas maltophilia*, and others. In such a situation, the most important method of protection is to treat the actual colonization taking into account local recommendations, but above all the regional sensitivity of microorganisms and the support of the patient's resistance tests for individual microorganisms (Pouch and Patel, 2019);
- opportunistic, environmental infections. Solid transplant recipients are sensitive to opportunistic infections, especially in the early post-transplant period. However, the difficulty in eradicating such infections is increased in the immunocompromised host.

Proposed procedures

Pneumocystis jirovecii pneumonia

The incidence of *Pneumocystis jirovecii* pneumonia (PJP) (Brakemeier et al., 2018) in solid transplant-recipients was estimated from 10% to 50% depending on the transplanted organ (Rodriguez and Fishman, 2004). The usual prophylactic drug is trimethoprim-sulfamethoxazole (TMP-SMX) ordered as a single dose 15–20 mg/kg/day, 3–7 times a week. In many programs, prophylaxis is continued for 6 months to 1 year. The extent of PJP prophylaxis can be offered to patients receiving prolonged higher degrees of immunosuppression, lung transplant recipients, or patients with recurrent respiratory tract infections (Iriart et al., 2015). Patients with confirmed hypersensitivity to TMP-SMX can be given the alternative PJP prevention with dapsone, pentamidine, or atovaquone (Rodriguez and Fishman, 2004). TMP-SMX prophylaxis is low cost, has low toxicity, and is effective in preventing many gastrointestinal, urinary, and respiratory tract infections caused by *T. gondii*, *Listeria* spp., *Cystoisospora belli*, and *Nocardia* spp.

Toxoplasmosis

Toxoplasmosis is uncommon but is a highly morbid infection after organ transplantation. The group with the highest risk of symptomatic infection is patients after heart transplantation, especially seronegative recipients of hearts from seropositive donors, whose risk of infection in the absence of prophylaxis is approximately 50–70%. The infection can present as cardiomyopathy, myocarditis, brain abscess, pneumonitis, and disseminated disease (Khurana and Batra, 2016).

The method for routine prevention of toxoplasmosis has not been stated; therefore, testing donors for toxoplasmosis, especially before heart transplantation, is especially important. Many centers suggest that seronegative recipients of seropositive cardiac transplants receive prophylaxis from 6 weeks to 6 months. In some procedures, lifetime prophylaxis is preferred (Derouin, Pelloux, and ESCMID Study Group on Clinical Parasitology, 2008). The basic drug used in prophylaxis is TMX-SMX due to its wide prevention profile (see above). In high-risk situations, combination therapies of TMX-SMX with dapsone are considered (Kittleson and Kobashigawa, 2013). Most alternative regimens (sulfadiazine, dapsone, atovaquone, clindamycin in combination with pyrimethamine or primaquine) have not been well studied in high-risk transplant populations; however, experiences based on other patient groups seem to be promising (Kittleson and Kobashigawa, 2013).

Cytomegalovirus

CMV may be acquired by solid transplant recipients from the donated organ, blood products transfused from a seropositive donor, or reactivation of endogenous infection. The highest risk of infection is seronegative recipients who receive transplanted organs from CMV-seropositive donors and CMV-seropositive recipients who require antilymphocyte antibodies in their therapy.

Many regional scientific associations recommend obligatory routine prophylaxis with ganciclovir or valganciclovir for high-risk recipients. The duration of antiviral therapy generally ranges from 3 to 12 months and often depends on the type of organ transplanted, the specific risk status of the patient, and individual institutional practice (Kotton et al., 2018).

Herpes simplex and varicella-zoster viruses

People who do not receive CMV prophylaxis should receive HSV and VZV prevention during the first 3–6 months after transplantation and during periods of lymphodepletion for treatment of rejection. HSV-specific prophylaxis should be considered for all HSV-1- and HSV-2-seropositive organ recipients who are not receiving antiviral medication for CMV prevention (Lee, Zuckerman, and AST Infectious Diseases Community of Practice, 2019).

Hematopoietic cell transplant recipients

The antimicrobial prophylaxis in HCT recipients is divided into:

- primary prophylaxis—to prevent infection in patients at increased risk;
- secondary prophylaxis—to prevent recurrent infection;
- preemptive therapy—starting antimicrobial therapy based on routine screening with sensitive assays (mostly PCR) to detect early some pathogens before the symptoms of infection and avoid progression to an invasive disease (Tomblyn et al., 2009).

Antimicrobial prophylaxis should be initiated at the beginning of the risk period, typically with the conditioning regimen or at the time of stem cell infusion. In the case of myelosuppressive antimicrobials, such as SMX-TMP, prophylaxis should begin at the time of engraftment and should be continued throughout the period with the highest risk of infection (Tomblyn et al., 2009).

Proposed procedures

Before engraftment

The decision about antibacterial prophylaxis depends on the type of HCT. Many authors suggest using a fluoroquinolone in high-risk neutropenic patients including allogeneic HCT recipients because the method reduces the risk of life-threatening infection. Risk is lower in autologous HCT recipients because of the shorter and less severe conditioning regimen; the decision about prevention is based on the analysis of individual case (Signorelli et al., 2020).

After engraftment

Antibacterial prophylaxis can be stopped at neutrophil engraftment, however, allogeneic HCT recipients who develop chronic graft-versus-host disease (GVHD) and have higher risk of severe infections with encapsulated bacteria (mainly *Streptococcus* spp.) may require prolonged administration of such prophylaxis. In such a situation, selection of the appropriate antibiotic should be based on local epidemiological recommendations, taking into account possible drug resistance (Frère et al., 2002).

Antifungal prophylaxis

HCT recipients are particularly susceptible to the occurrence of invasive fungal infections, especially *Candida* spp. and *Aspergillus* spp., which can be observed mainly in the pre-engraftment period. The choice of regimen depends on the type of transplant performed, possible primary patient infections, the patient's tolerance to the therapy, and possible interactions with the applied peri-transplant treatment.

In myeloablative allogeneic HCT recipients without special indications for mold prophylaxis and in autologous HCT recipients, who can develop severe mucositis, using oral fluconazole is recommended. For patients who need anti-mold prophylaxis, voriconazole and posaconazole are favored (Wingard et al., 2010).

Pneumocystis jirovecii pneumonia (PJP)

PJP prophylaxis should be recommended for both allogeneic and autologous HCT recipients. It can be started after the neutrophil engraftment and continued during the whole immunosuppressive therapy, typically for 6 months, but for even longer in patients who develop GVHD (Redjoul et al., 2019). The preferred regimen for PJP is TMP-SMX, based on its effectiveness in other infections. It is continued until immunosuppressive therapy is completed.

Toxoplasmosis

Toxoplasmosis is a rare parasitic infection in HCT recipients, mainly in the allogeneic group. Prophylactic administration of TMX-SMP, as with PJP prophylaxis, simultaneously protects patients against *T. gondii* infection. Alternative therapy with pyrimethamine, sulfadiazine with leucovorin can be considered in patients with contraindications for TMX-SMP, however, their use has not yet been sufficiently researched (Gajurel et al., 2015).

Mycobacterium tuberculosis

This prophylaxis is recommended only for patients with a high risk of tuberculosis (TB) reactivation after HCT, like people who:

- had been exposed to individuals with active pulmonary or laryngeal tuberculosis, regardless of the HCT candidate's or recipient's tuberculin skin test (TST) or interferon-gamma release assay (IGRA) status;
- have a positive TST result, regardless of TB vaccination status, without previous treatment for latent TB and with no evidence of active TB;
- have a positive IGRA result, without previous treatment for latent TB and with no evidence of active TB.

In these groups of HCT patients, prophylaxis with isoniazid can be used. Because of drug interactions with mold-active azoles, which can lead to increased toxicity, concomitant drug administration should be avoided (Lewalle et al., 2019).

Cytomegalovirus

The risk of CMV reactivation depends on the type of HCT (significantly higher in allogeneic than in autologous HCT recipients) and the serological status of the donor and recipient (the lowest is for transplantation from a CMV-negative donor to a CMV-negative recipient and the highest if for seropositive recipients; Holt, 2019). The risk factors are also using antithymocyte globulin and/or a high dose of steroids and GVHD development (Ljungman et al., 2019).

Primary prevention is realized by selection of a CMV-seronegative donor for CMV-seronegative recipients when possible and using blood products from seronegative donors or products that are depleted of leukocytes. Another method of prophylaxis that is preferred by many physicians is preemptive viral identification by routine PCR testing for CMV and HCT recipient monitoring.

CMV prophylaxis can be realized with a variety of drugs, including ganciclovir, valganciclovir, letermovir, foscarnet, acyclovir, and valacyclovir. The most common procedures are:

- ganciclovir 5 mg/kg IV every 12 h;
- valganciclovir 900 mg orally twice daily for patients who tolerate oral therapy, especially, if they have low risk for CMV disease and low viral loads;
- foscarnet 60 mg/kg IV every 8 h is an alternative for patients who cannot take ganciclovir or valganciclovir.

Pre-emptive therapy is continued for a minimum of 2 weeks with weekly PCR monitoring. If CMV viremia is no longer detected, treatment can be stopped but monitoring is continued. If CMV is still detected at 2 weeks but the viral load is declining, maintenance dosing should be given until CMV is no longer detectable (Ljungman et al., 2019). The common side effects of ganciclovir and valganciclovir are renal dysfunction and neutropenia.

Herpes simplex virus

All HCT recipients who are seropositive for HSV-1 or HSV-2 should get antiviral prophylaxis during the early transplant period. It usually begins when the conditioning regimen is started and continues until engraftment or until mucositis resolves, usually up to 30 days after the transplant. Acceptable options for HSV prophylaxis include:

- intravenous acyclovir 5 mg/kg every 12 h or 250 mg/m² every 12 h;
- oral acyclovir 400 or 800 mg twice daily;
- oral valacyclovir 500 mg twice daily (Tomblyn et al., 2009).

Varicella-zoster virus

VZV is an important factor that leads to severe diseases mostly due to reactivation of endogenous virus in seropositive recipients during the first year after HCT. All VZV-seropositive allogeneic and autologous HCT recipients should be given an oral prophylaxis regimen of valacyclovir (500 mg twice daily) or acyclovir (800 mg twice daily) for 1 year following transplantation. Patients who cannot take oral medications should be given acyclovir 5 mg/kg IV every 12 h (Tomblyn et al., 2009).

Epstein-Barr virus

EBV reactivation usually results from endogenous reactivation or transmission from the allograft and may be asymptomatic, cause a mononucleosis syndrome, or progress to a life-threatening EBV-related post-transplantation lymphoproliferative disorder. Patients with high risk for EBV reactivation should be monitored weekly by PCR on the day of transplantation and until 3 months after the procedure. The prevention strategy includes reduced immunosuppression, administration of the anti-CD20 monoclonal antibody, and administration of EBV-specific cytotoxic T cells (Tomblyn et al., 2009).

Human herpes virus 6

Reactivation is most frequent within the first month following HCT, however, specific prophylaxis against HHV-6 is not recommended because of the low risk of symptomatic disease and toxicity of antiviral drugs.

Preexposure prophylaxis in surgery

Surgical site infections (SSIs) are a common problem in infections connected with health care. The official criteria set by CDC (2017a,b) define an SSI as an infection related to an operative procedure that occurs at or near the surgical incision within 30–90 days if prosthetic material is implanted during surgery. The human and financial costs of SSIs are actually growing; therefore, it is extremely important to carry out PrEP to reduce risks (Borchardt and Tzizik, 2018). Surgical wound classification has been developed for infectious risk assessment, perioperative protocol development, and surgical decision-making (Table 1) (Ortega et al., 2012).

Antimicrobial prophylaxis prevents SSIs by reducing infective microorganisms at the surgical site during the operative procedure, so it is administered when there is a higher risk of an SSI. The patient-related risk factors for SSI are: age, obesity, cachexia, tobacco use, immunosuppression, corticosteroid therapy, prolonged hospitalization, coexistent infections, and antibiotic therapy.

Proposed procedures

The best time for prophylactic antibiotics is 1–2 h before initial incision. Because the time frame during which antibiotics can be given is very short, the risk of *Clostridium difficile* development and drug resistance is low. The first-line prophylaxis is cefazolin, which has a wide spectrum against the organisms often found in surgery. The antibiotic is active against streptococci,

Table 1 Surgical wound classification for infectious risk assessment.

<i>Wound classification</i>	<i>Definition</i>	<i>Risk of SSI</i>
Clean	Uninfected operative wounds without inflammation, without opening viscus and the wound is closed primarily.	1–5%
Clean-contaminated	Uncontaminated unusually operative wounds in which a viscus is entered under controlled conditions.	3–11%
Contaminated	Open, fresh accidental wounds, operations with major breaks in sterile technique, or gross spillage from a viscus. Wounds in which acute, nonpurulent inflammation was encountered also are included.	10–17%
Dirty	Old traumatic wounds with retained devitalized tissue, foreign bodies, or fecal contamination or wounds that involve existing clinical infection or perforated viscus.	Over 27%

Adapted from Ortega G, Rhee DS, Papandria DJ, et al. (2012) An evaluation of surgical site infections by wound classification system using the ACS-NSQIP. *Journal of Surgical Research* 174(1): 33–38.

methicillin-sensitive *S. aureus*, and many gram-negative organisms (Leaper and Edmiston, 2017). Alternative prophylaxis includes intravenous vancomycin and clindamycin, which are not used routinely and are left only for selected situations like a patient colonized by MRSA or at a high risk of MRSA colonization (Peel et al., 2019).

Antibiotics should be started in standardized doses at least 60 min before surgical incision to optimize the adequate tissue concentration at the time of the initial incision (the half-life of antibiotics should be considered). If prophylaxis is continued after surgery, the duration should not be longer than 24 h (Berríos-Torres et al., 2017). The choice of antibiotic and its dosages for PrEP depends on the type of surgery and recommendations of national scientific societies.

Preexposure vaccinations

Preexposure prophylaxis realized with vaccinations is used for people who have a high risk of infection, commonly connected with job-related activities or traveling to some countries. The prevention strategies should be individualized according to specific environmental conditions, preexisting health factors, and behaviors that are unique to the patient. Many countries have special vaccination programs specifically for health care workers (Maltezou et al., 2019).

Depending on the type of pathogen, the risk may be:

- continuous, for example, people with an occupational risk of infection, such as employees of microbiological and virological laboratories and health professionals;
- temporary, related to traveling to areas with high incidence of some infections or poor access to post-exposure medical procedures, among other factor (Freedman and Chen, 2019).

The vaccination procedure must be safe for the patient and highly immunogenic. Table 2 presents the proposed procedures.

Preexposure immunoglobulins

The use of exogenously produced immunoglobulins to prevent infectious diseases has a wide range of possibilities. In nature, such protection concerns the fetus and then the newborn, who are protected against infections by intrauterine transfer of maternal immunoglobulin G (IgG) during the second half of pregnancy. Due to such protection, newborns, although without their own immunity, do not become infected: They defend themselves with maternal antibodies. Observations regarding the effectiveness of this phenomenon have been used in the production of medical preparations containing immunoglobulins pooled from blood donors.

Proposed procedures

There are two types of antibody preparations available.

The first is standard polyvalent immunoglobulin of human origin, obtained from pooled human plasma from screened donors contains mainly IgG with small amounts of IgA and IgM. This product is used as IgG replacement therapy in patients with immunological deficiencies characterized by absent or deficient antibody production to protect against life-threatening infections (Tangye et al., 2020).

The second is specific immunoglobulins of human or animal origin, or produced by recombinant DNA technology that contain high amounts of specific IgG antibodies against a particular pathogen. The product contains hyperimmune globulins, which are used in specific exposures, mostly in PEP. Using immunoglobulins in PrEP is limited only to a few products in very specific groups of patients, like:

- hepatitis B immune globulin (HBIG)
 - infants born to a hepatitis B virus (HBV)-infected mother,
- HAV-PrEP via passive immunization
 - as an isolated treatment
- Infant travelers <6 months of age
- Travelers for whom vaccine is contraindicated (e.g., allergic to HAV vaccine);
 - the combined prevention vaccine plus immunoglobulin
- Adult travelers >40 years, based on the provider's risk assessment.
- Children >6 months and adults with high risk of severe HAV manifestation or transmission following exposure;
- Individuals >6 months with chronic liver disease;
- Immunocompromised individuals >6 months (Nelson et al., 2020).

Postexposure prophylaxis

Chemotherapy

Chemoprophylaxis of invasive meningococcal disease

Neisseria meningitidis is a gram-negative bacterium that is found on the mucosa of the nasopharynx in approximately 10% of healthy people. Invasive meningococcal disease (IMD) is a severe form of *N. meningitidis* infection, most commonly manifested as sepsis

Table 2 Preexposure vaccinations.

	<i>Risk population</i>	<i>Standard primary schedule</i>	
Hepatitis A (Centers for Disease Control and Prevention, 2017b)	– Persons traveling or temporarily residing in the countries with high and intermediate HAV endemicity; – All children at 1 year of age; – Children and adolescents 2–18 years of age who live in areas with high disease incidence; – Men who have sex with men; – Patients who use illegal drugs (both injection and non-injection); – Persons with occupational risk factors (working with HAV-infected primates or with HAV virus in a laboratory setting); – Persons with chronic liver disease or who have received/are awaiting liver transplants; – Persons with clotting-factor disorders; and close contacts of adopted children from countries with increased incidence of HAV infection	Recommended to patients older than 12 months, in two dosages: 0, 6–12 months.	Life-long immunity
Hepatitis B (Schillie et al., 2018)	– Persons at risk for occupational exposure to HBV; – Household contacts; – Injection-drug users; – Sexual (heterosexual and MSM) exposure; – Developmentally disabled persons in long-term-care facilities; – Correctional facilities; – Hemodialysis patients; – Persons with HCV; – Persons with chronic liver disease; – Travelers to countries where HBV is endemic; – Persons with HIV; – Persons with diabetes.		
Rabies (Kessels et al., 2017)	– People who work with rabies in laboratories, animal control and wildlife offices; – People traveling to countries with a high risk of catching rabies who will be in close contact with wild and domestic animals, especially in areas with poor access to medical services	Three doses of vaccine given on days 0, 7, 21–28.	Any booster doses of the vaccine depend on the level of antibodies, which should be monitored regularly depending on the level of exposure.
Japanese encephalitis		Two doses: day 0; second dose any time between day 7 and day 28.	A single booster >1 year after completion of primary series if ongoing risk.
Meningococcal (Mbaeyi et al., 2020)	– People traveling to or living in areas at risk of <i>Neisseria meningitidis</i>; – People with an immunodeficiency that increases the risk of meningococcal disease (asplenia, HIV infection, complement component deficiency)	Serotypes: A, C, Y, W135: patients 6 weeks to 6 months: 2 dosages; older than 6 months: single dose; Serotype B: patients older 2 months: 2 doses	Life-long immunity
Typhoid	– Travelers to areas with a risk of exposure to <i>S. Typhi</i>.	PO: 1 cap every other day × 4 doses. IM: Single dose.	PO: Repeat every 5 years if ongoing risk. IM: Repeat every 2 years if ongoing risk.
Yellow fever (YF)	– People traveling to or living in areas at risk for YF transmission in South America and Africa	Recommended to patients older than 9 months; in one dosage.	Life-long immunity
Cholera (Wong et al., 2017)	– Prevention of cholera caused by serogroup O1 in adults 18 through 64 years of age traveling to affected areas who are at immediate risk of epidemic cholera.	Single dose	No specific recommendation; consider booster dose every 6 months if at continued risk. As of December 2020, the producer of the cholera vaccine will temporarily stop making and selling this vaccine; the vaccine may be in limited supply or unavailable (https://wwwnc-1cdc-1gov-1oaxngsr401a7.han.ump.edu.pl/travel/diseases/cholera).
Influenza	– Annual immunization of health care providers; – People with high risk of severe influenza	One dose every year (only the children below 9).	Every year
Pertussis (Centers for Disease Control and Prevention (CDC), 2012)	– All adults, including those aged 65 and older, regardless of the time since their last Td dose; – Health care personnel.	One dose	
Varicella (Anon, 1997)	– Health care providers	Two doses	Life-long immunity

and/or purulent meningitis. The incidence of IMD is estimated from 0.3 to 3 per 100,000 residents in developed countries (Halperin et al., 2012) and from 10 to 25 per 100,000 residents in some developing countries (Deuren et al., 2000). The disease often begins with non-specific symptoms such as high fever, severe weakness, and vomiting. In the absence of proper treatment, it quickly leads to serious coagulation disorders, which are manifested by rapidly progressive hemorrhagic rash (Bosis et al., 2015). Rapid deterioration of the patient's condition can lead to death within the first 24–48 h after onset (Łyczko and Borger, 2020). About 5–20% of patients with IMD develop full-blown sepsis with high mortality of up to 20–80% (Deuren et al., 2000). Meningococcal meningitis results in a lower rate of morbidity of 18–55%. Nonetheless, 11–19% of survivors experience serious sequelae (e.g., neurologic disability, limb loss, and hearing loss; Bilukha, Rosenstein, and National Center for Infectious Diseases and Centers for Disease Control and Prevention (CDC), 2005).

Infection caused by *N. meningitidis* spreads with droplets. The risk of developing IMD for household contacts exposed to patients who have sporadic meningococcal disease was estimated to be 4 per 1000 exposed people, which is 500–800 times greater than the risk for the total population (Bilukha, Rosenstein, and National Center for Infectious Diseases and Centers for Disease Control and Prevention (CDC), 2005). The risk for health care providers exposed to infected patients was estimated by Gilmore et al. (2000) as 0.8 per 1,000,000 people, which is 25 times higher than for the general population. The aim of IMD chemoprophylaxis is to prevent illness among close contacts.

Proposed procedures

Following CDC recommendations, the strategy of meningococcal prophylaxis should be implemented within 24 h after contact or identification of the pathogen. In the case of a delayed report of IMD, chemoprophylaxis can be given up to 14 days from the disease onset. The decision about chemoprophylaxis should not be based on nasopharyngeal culture (Bilukha, Rosenstein, and National Center for Infectious Diseases and Centers for Disease Control and Prevention (CDC), 2005).

The indications for chemoprophylaxis implementation are as follows (Bilukha, Rosenstein, and National Center for Infectious Diseases and Centers for Disease Control and Prevention (CDC), 2005):

- close contact with a patient within 7 days before the disease onset, regardless of vaccination status. Close contact applies to: household members living with a sick person, people who are in intimate contact with the patient, or people sleeping in the same bedroom with the patient (students, soldiers, officers);
- people who have been in direct contact with secretions from the patient's respiratory tract during medical procedures, including mouth-to-mouth resuscitation, suctioning, and endotracheal intubation, up to 24 h after antimicrobial therapy was initiated;
- people traveling with the patient in the same plane, ship, bus, or car for longer than 8 h. For travelers, antimicrobial chemoprophylaxis should be considered for any passenger who had direct contact with respiratory secretions from an index patient or for anyone seated directly next to an index patient on a prolonged flight (i.e., one lasting >8 h; CDC, 2000);
- the patient themselves before discharge from a hospital if they were not treated with ceftriaxone.

Regimen

Rifampin, ciprofloxacin, and ceftriaxone are 90–95% effective in reducing nasopharyngeal carriage of *N. meningitidis* and are all acceptable antimicrobial agents for chemoprophylaxis (CDC, 2000). The dosages for specific age groups and duration of administration are presented in Table 3.

Rifampicin

Rifampicin can be used in all age groups. Contraindications to this antibiotic are: pregnancy, nursing mothers, jaundice, and hypersensitivity to the drug. Rifampicin is an intense inducer of the hepatic P450 cytochrome enzyme system; therefore, the drug increases the metabolism of many drugs. Patients undergoing long-term anticoagulation therapy with warfarin have to increase their dosage (Holstege, 2014).

Table 3 Recommended chemoprophylaxis regimens for protection against meningococcal disease—Advisory Committee on Immunization Practices (ACIP), United States, 2012.

Drug	Age group	Dosage	Administration	
			Route	Duration
Rifampin	Children aged <1 months	5 mg/kg every 12 h	Oral	2 days
	Children aged ≥1 months	10 mg/kg every 12 h		
	Adults	600 mg every 12 h		
Ciprofloxacin	Adults	500 mg	Oral	Single dose
Ceftriaxone	Children age < 15 years	125 mg	Intramuscular	Single dose
	Adults	250 mg		

Ceftriaxone

Ceftriaxone can be used in every age group, and it is a first-line antibiotic recommended as chemoprophylaxis for IMD in children, pregnant women, and nursing mothers. The antibiotic has few contraindications for use: documented hypersensitivity and hyperbilirubinemia in neonates (especially premature; Zeng et al., 2017).

Ciprofloxacin

Ciprofloxacin can be used only in people older than 16 years. Contraindications to ciprofloxacin include patients with documented hypersensitivity to the drug or components of the formulation. The concurrent administration of tizanidine for muscle spasms is also a contraindication. Patients with myasthenia gravis should avoid ciprofloxacin because it may exacerbate muscle weaknesses (Thai et al., 2020).

Some regions of the world have documented resistance of *N. meningitidis* to ciprofloxacin and/or rifampicin (Taha et al., 2006). Local societies can update these recommendations regarding which antibiotics to use for IMD chemoprophylaxis based on regional resistance data. Although the recommended chemoprophylaxis effectiveness reaches up to 90–95%, it does not provide 100% protection against the disease. Patients who have received IMD antibiotic prophylaxis should be informed about the symptoms of the disease and the need to report to the hospital immediately in case they occur.

Chemoprophylaxis of invasive *Haemophilus influenzae* serotype b disease

Haemophilus influenzae serotype b (Hib) was one of the most common causes of bacterial meningitis and a frequent cause of other invasive diseases (e.g., epiglottitis, pneumonia, septic arthritis, and bacteremia), particularly in early childhood, before the conjugated vaccine program. Vaccination has radically reduced the incidence of invasive *H. influenzae* serotype disease (IHibD) in children. However, IHibD remains a problem in countries that do not use the vaccine (CDC, 2002a,b). Secondary cases of Hib disease (illness occurring within 60 days of contact with a patient) occur but are rare. Secondary attack rates are higher among household contacts aged <48 months (2.1%), especially those aged <12 months (6%) and <24 months (3%) (Wenger and Ward, 2003)

Proposed procedures (Briere et al., 2014)

IHibD chemoprophylaxis is recommended for:

- patients who are treated with an antibiotic other than cefotaxime or ceftriaxone and are aged <2 years or live in a household with a child <4 years of age who had not received an age-appropriate number of doses of Hib conjugate vaccine, or immunocompromised children should receive rifampin prior to hospital discharge (American Academy of Pediatrics, 2018a). Because cefotaxime and ceftriaxone eradicate Hib colonization, prophylaxis is not needed for patients treated with these antibiotics (Goldwater, 1995);
- all household contacts, who:
 - have had at least one contact <4 years of age who had not received an age-appropriate number of doses of Hib conjugate vaccine;
 - has a child <12 months of age who had not completed the primary Hib series;
 - has a contact <18 years who is immunocompromised, regardless of that child's Hib immunization status.

A household or close contact is defined as a person who resides with the index patient or who had spent ≥ 4 h with the index patient for at least 5 of the 7 days before the day of hospital admission of the index case (American Academy of Pediatrics, 2018a).

Chemoprophylaxis is recommended in child care settings when two or more cases of IHibD have occurred within 60 days and unimmunized or underimmunized children attend the facility (Briere et al., 2014).

Regimen

Rifampin 20 mg/kg orally (maximum dose 600 mg) once per day for 4 days is the regimen of choice for Hib chemoprophylaxis in individuals ≥ 1 month. Drugs other than ceftriaxone and cefotaxime that are used to treat *H. influenzae* infections, such as ampicillin, second-generation cephalosporins, and TMP-SMX, are not effective for chemoprophylaxis because they do not reliably eradicate Hib from the nasopharynx. Using these agents for antimicrobial prophylaxis against IHibD is not recommended.

In addition to IHibD chemoprophylaxis, exposed unimmunized or incompletely immunized children who are household, child care, or preschool contacts of patients with IHibD who got IHibD prophylaxis must be observed for any symptoms of illness (American Academy of Pediatrics, 2018a).

Chemoprophylaxis of pertussis

Prophylactic administration of drugs to the people of the close contact is implemented as soon as pertussis is diagnosed in a patient, not later than 21 days from the beginning of the cough. It is recommended to administer antibiotics, mainly macrolides, in analogous schemes as in the pertussis therapy.

Proposed procedures

PEP of pertussis is recommended for:

- **all household contacts** within 21 days of onset of cough in the index patient (Tiwari, Murphy, Moran, and National Immunization Program, CDC, 2005; Cramer and Heininger, 2008).

- high-risk people—those who are personally at high risk of developing severe illness, or who will have the close contact with people at high risk of severe illness—within 21 days of exposure to an infectious pertussis case (Tiwari, Murphy, Moran, and National Immunization Program, CDC, 2005).

Regimen

The dosages for specific ages group and duration of administration are presented in Table 4.

Specific antimicrobial agents

Azithromycin is only one drug that can be given for prophylaxis in small infants <1 month of age. The most common side effects are gastrointestinal problems—nausea, vomiting, and diarrhea—but they are not too traumatic and many patients can continue therapy (Ballow and Amsden, 1992). The contraindications for azithromycin are hypersensitivity to macrolides and a history of cholestatic jaundice/hepatic dysfunction associated with prior azithromycin use.

Chemoprophylaxis of Lyme disease

Lyme disease, a spirochetal infection caused by *Borrelia* spp. and transmitted by *Ixodes ricinus* ticks, is the most common tick-borne disease in the United States and Europe. The duration of tick attachment is very important in assessing the risk of transmission because *Borrelia* spp. are rarely transferred within the first 48 h of arachnid connection (Sutton and Spry, 2019).

Proposed procedures

The first method of prevention is early removal of ticks, within 24–36 h (Wormser et al., 2006; Sutton and Spry, 2019). Prophylaxis might be considered if the patient had visited the local region with high risk of infection and meets **all** five criteria defined by the Infectious Diseases Society of America (Wormser et al., 2006) (Table 5). If any of these criteria are not met, watchful waiting for 30 days has been recommended to monitor the appearance of fever, arthralgia, and rash (Smith et al., 2012).

Regimen

If the patient meets all of the aforementioned criteria (Table 5), the recommended dose of doxycycline is 200 mg for adults and 4.4 mg/kg up to a maximum dose of 200 mg in children, given as a single dose. The American Academy of Pediatrics (2018b) states

Table 4 Recommended chemoprophylaxis regimens for protection against pertussis (Tiwari, Murphy, Moran, and National Immunization Program, CDC, 2005).

Age group	Azithromycin	Erythromycin	Clarithromycin	TMP-SMZ
Infants < 1 month	10 mg/kg/day for 5 days	Not preferred because of risk for IHPS	Not recommended	<2 months: contraindicated (risk of kernicterus)
Infants 1–5 months	10 mg/kg/day for 5 days	40–50 mg/kg/day in 4 divided doses for 14 days.	15 mg/kg/day in 2 divided doses each day for 7 days.	≥ 2 months TMP—8 mg/kg/day, SMZ—40 mg/kg/day in 2 divided doses for 14 days.
Infants and children aged ≥ 6 months	10 mg/kg (maximum: 500 mg) on day 1, followed by 5 mg/kg/day (maximum: 250 mg) on days 2–5.	40–50 mg/kg/day (maximum: 2 g/day) in 4 divided doses for 14 days.	15 mg/kg/day (maximum: 1 g/day) in 2 divided doses each day for 7 days.	TMP—8 mg/kg/day, SMZ—40 mg/kg/day in 2 divided doses for 14 days.
Adults	500 mg on day 1, followed by 250 mg/day on days 2–5.	2 g/day in 4 divided doses for 14 days	1 g/day in two divided doses for 7 days.	TMP—320 mg/day, SMZ—1600 mg/day in 2 divided doses for 14 days.

TMP, trimethoprim; SMZ, sulfamethoxazole; IHPS, infantile hypertrophic pyloric stenosis.

Table 5 Criteria for antibiotic prophylaxis against Lyme disease following a tick bite (Wormser et al., 2006).

Antibiotic prophylaxis should be used only in patients who meet **ALL** of the following criteria

Attached tick identified as an adult or nymphal *Ixodes scapularis* tick
 Tick is estimated to have been attached for ≥ 36 h
 Prophylaxis is begun within 72 h of tick removal
 Local rate of infection of ticks with *B. burgdorferi* is ≥ 20% (these rates of infection have been shown to occur in parts of New England, parts of the mid-Atlantic States, and parts of Minnesota and Wisconsin)
 Doxycycline is not contraindicated (i.e., the patient is not <8 years of age, pregnant, or lactating)

The recommended dose of doxycycline is 200 mg for adults and 4 mg/kg up to a maximum dose of 200 mg in children ≥ 8 years, given as a single dose. This regimen has never been tested in children; this recommendation is extrapolated from experience in adults.

that in areas of high risk, a single prophylactic dose of doxycycline can be used in children of any age to reduce the risk of acquiring Lyme disease, but the efficacy of this approach and the appropriate regimen have not been established and recommendations were extrapolated largely from the adults experience.

The decision to select prophylaxis in countries other than the United States should be based on local recommendations and knowledge of the contamination of areas by the *Borrelia* spp.

Tularemia

Tularemia is a bacterial zoonosis caused by *Francisella tularensis*, one of the most infectious pathogenic bacteria. The disease occurs throughout much of North America, Europe, and Asia. *F. tularensis* can infect humans through the skin, mucous membranes, gastrointestinal tract, and lungs. Most clinical cases involve chronic lymphadenopathy associated with a skin, mucosa, or conjunctival inoculation lesion. Less frequently, patients suffer from systemic diseases and severe pneumonia with mortality rates up to 60% (Gill and Cunha, 1997).

Proposed procedures

Tularemia prophylaxis is recommended only in cases of laboratory exposure to infectious materials. Management options for potentially exposed workers include a fever watch or antimicrobial prophylaxis. There are no set criteria for determining who should be managed by observation and who would benefit from immediate prophylaxis. Factors to consider when making this decision include:

- nature of the exposure—workers who report the procedures generating aerosols are probably at greater risk than those who simply worked with the organism on the bench;
- incubation period—the typical incubation period for tularemia is 3–7 days. Much of this period may have passed by the time the organism is positively identified, in which case the remaining risk of infection is low;
- level of concern (Kirimanjeswara et al., 2007).

Regimen (Dennis et al., 2001)

Doxycycline 100 mg orally every 12 h over 14 days is generally recommended for prophylaxis in adults. Ciprofloxacin 500 mg every 12 h over 14 days is not FDA approved for prophylaxis of tularemia but has demonstrated efficacy in various studies, and thus it may be an alternative for patients unable to take doxycycline.

Invasive group A streptococcal prophylaxis

Invasive group A streptococci (GAS) are some of the most common bacteria encountered daily, and they result in acute infections with a wide array of manifestations in both adults and children. These microorganisms are responsible for an estimated 9000–12,000 deaths per year in the United States (Newberger and Gupta, 2021). The most common clinical presentations of GAS infections are toxic shock syndrome, with or without a focus of infection, necrotizing fasciitis or myositis, bacteremia with no septic focus, and pneumonia (Moore et al., 2019). People who are in the close contact with a case of invasive GAS have a high likelihood of becoming colonized with a virulent strain. The risk of subsequent invasive GAS disease in this group is 200–2000-fold higher than the risk among the general population (Lamagni et al., 2015).

Proposed procedures

Decisions regarding administration of GAS prophylaxis depend on the type of exposure, the immune status of the contact, and local recommendations (Health Protection Agency, Group A Streptococcus Working Group, 2004). Significant exposures include close family members, people who are kissing or sleeping in the same bed, and caretakers who spend many hours daily with an infected individual. Prophylaxis is warranted for people who are pregnant, immunosuppressed, who recently had surgery, or who have any open wound (Moore et al., 2019).

Chemoprophylaxis should only be given to people who have been exposed during the 7 days before the onset of symptoms of GAS to 24 h after initiating antimicrobial therapy in the case. It should be started as soon as possible, preferably within 24 h of identifying the case, but is still recommended up to 7 days after the last contact with the case (Moore et al., 2019).

Regimen

According to Canadian and American recommendations, the first choice in GAS prophylaxis are cephalexin and cefadroxil (Table 6). All people who receive chemoprophylaxis should watch for signs and symptoms of invasive GAS disease for 30 days after the diagnosis of invasive disease in the household contact (Public Health Agency of Canada, 2006).

Influenza chemoprophylaxis

Influenza is an acute respiratory disease caused by influenza A or B and sometimes influenza C viruses. The virus causes seasonal epidemics around the world. In most cases, the disease is self-limiting, but in some patients it may cause life-threatening complications, such as pneumonia and myocarditis. The actual list of patients with the high risk of influenza complications were have been extracted by CDC (2021a) (Table 7).

Table 6 Recommended GAS chemoprophylaxis regimens.

Drug	Dose	Duration
First-line choice		
Cephalexin	25 mg/kg to 50 mg/kg daily, to a maximum of 1 g/day, in two to four divided doses for 10 days	10 days
Cefadroxil	25 mg/kg to 50 mg/kg daily, to a maximum of 1 g/day, in two divided doses (children) or once daily (adults)	
second-line choice		
Clarithromycin	Adults: 250 mg orally twice daily Children: 15 mg/kg daily, in divided doses every 12 h, to a maximum of 250 mg orally twice daily	10 days
Clindamycin	Adults: 150 mg every 6 h Children: 8–16 mg/kg daily, divided into three or four equal doses, to a maximum of 600 mg daily	10 days Alternative for persons who are unable to tolerate beta-lactam antibiotics

Adapted from Public Health Agency of Canada (2006) Guidelines for the prevention and control of invasive group A streptococcal disease. *CDCR* 32S2: 1–26.

Table 7 Groups at high risk for serious influenza complications.

Children <5 years, but especially <2 years
Adults ≥65 years of age
Women who are pregnant or up to 2 weeks postpartum
Residents of nursing homes and long-term care facilities
People from certain racial and ethnic minority groups: non-Hispanic Black persons, Hispanic or Latino persons, and American Indian or Alaska Native persons
People with medical conditions including:
• Asthma
• Neurologic and neurodevelopmental conditions (including disorders of the brain, spinal cord, and peripheral nerve and muscle such as cerebral palsy, epilepsy, stroke, intellectual disability, moderate-to-severe developmental delay, muscular dystrophy, and spinal cord injury)
• Chronic lung disease (e.g., chronic obstructive pulmonary disease, cystic fibrosis)
• Heart disease (e.g., congenital heart disease, congestive heart failure, coronary artery disease)
• Blood disorders (e.g., sickle cell disease)
• Endocrine disorders (e.g., diabetes mellitus)
• Kidney disorders
• Liver disorders
• Metabolic disorders (e.g., inherited metabolic disorders and mitochondrial disorders)
• Weakened immune system due to disease (e.g., HIV, AIDS, cancer) or medication (e.g., chemotherapy or radiation therapy, chronic glucocorticoids)
• Children <19 years of age who are receiving long-term aspirin therapy
• People with extreme obesity (body mass index [BMI] ≥40)

Adapted from Centers for Disease Control and Prevention (2021b) *People at High Risk of Flu*. <https://www.cdc.gov/flu/highrisk/index.htm>.

Proposed procedure

Routine flu prophylaxis is not recommended as the standard of care, but it should be strictly considered in relation to:

- people at high risk of influenza complications who have been exposed to an individual with influenza within the previous 48 h, and for whom influenza vaccination is contraindicated, unavailable, or expected to have low effectiveness;
- during influenza outbreaks in long-term care facilities in older adults and chronically ill residents regardless of prior influenza vaccination;
- unvaccinated patients with the high risk for influenza complications during the first 2 weeks following vaccination after exposure to a person with influenza if the exposure had occurred within the previous 48 h;
- people who are unvaccinated household contacts of people with a high risk for flu complications **and** who had household exposure to an individual with influenza within the previous 48 h (Uyeki et al., 2019).

Regimen

Two classes of antiviral drugs are available for the prevention of influenza:

- neuraminidase inhibitors, zanamivir and oseltamivir, which are active against both influenza A and B;
- adamantanes, amantadine and rimantadine, which are active only against influenza A. Due to this limited virus susceptibility, these drugs should not be used in the prevention of influenza, except in exceptional clinical circumstances.

The recommended dosage, route of administration, and duration of influenza chemoprophylaxis, according to CDC (2021b) recommendations, are presented in Table 8.

Table 8 Recommended dosage, route of administration and duration of influenza chemoprophylaxis (CDC, 2021b).

Drug	Route of administration	Dosage	Duration
Oseltamivir	Oral	<3 months: oseltamivir chemoprophylaxis is not recommended except critical situation due to limited data in this age group 3–12 months: 3 mg/kg/dose once a day (Kimberlin et al., 2013) >1 year: dose varies by child's weight: <15 kg: 30 mg once a day; >15–23 kg: 45 mg once a day; >23–40 kg: 60 mg once a day; >40 kg: 75 mg once a day. Adults: 75 mg once a day	7 days (can be prolonged up to 14 days in close household contact)
Zanamivir (used if oseltamivir-resistant influenza is suspected)	Inhalatory	<5 years not recommended >5 years: 10 mg [2 inhalations] once daily	

Oseltamivir is an antiviral drug recommended for prophylaxis in children and adults. Following metabolism to the active metabolite, oseltamivir carboxylate inhibits viral neuraminidase, blocking the release of progeny virions from infected cells and viral entry into uninfected cells. Initiation of oseltamivir prophylaxis within 48 h of close contact with the influenza case reduce the risk of infection with 89% protective efficacy (Welliver et al., 2001). The main side effects of oseltamivir are related to gastrointestinal symptoms (Dobson et al., 2015). Rare occurrences of neuropsychiatric side effects and the risk of suicide have been reported primarily in children and adolescents taking oseltamivir in therapeutic dosages (Harrington et al., 2018; Huh et al., 2020). Oseltamivir is considered the drug of choice for chemoprophylaxis in the pregnant women who have had close contact with someone likely to have been infectious with influenza (ACOG Committee Opinion No. 753 Summary, 2018).

Zanamivir chemoprophylaxis is used to control household exposure and institutional outbreaks of influenza A or B when circulating strains are suspected of being resistant to oseltamivir (Uyeki et al., 2019).

Because of high rates of adamantane drug resistance in viral influenza strains, using amantadine and rimantadine for the prevention or treatment of influenza is contraindicated (Hussain et al., 2017).

New drugs like baloxavir and peramivir are not recommended in influenza prophylaxis due to the lack of data unambiguously confirming their effectiveness. However, research that has been conducted on baloxavir has shown promising results in the high-risk pediatric group (Ikematsu et al., 2020).

Varicella-zoster virus infections

Antiviral prophylaxis with acyclovir or valacyclovir can be used to prevent clinical VZV infection after an exposure for the patients who cannot receive vaccination or specific anti-VZV immunoglobulin. The potential target group for this kind of VZV-PEP are immunocompromised patients and/or pregnant women, but the decision must be individual after analyzing a specific case. CDC does not recommend acyclovir for prophylactic use among healthy children, adolescents, or adults without evidence of immunity after exposure to varicella. Vaccination is the method of choice in these situations. No studies have been conducted regarding prophylactic use of acyclovir among immunocompromised people; therefore, VZV-specific immunoglobulin is recommended in these situations (Marin et al., 2007).

Proposed procedure

This PEP should be initiated on day 7–10 after exposure and continued for 7 days. The delay in prophylaxis allows for early viral replication and may allow the exposed patient to develop some immunity without developing symptomatic disease. However, in some groups of patients, especially HCT or solid organ recipients, some experts suggest to prolong the course of VZV PEP (Marin et al., 2007; Tomblyn et al., 2009).

Regimen

Table 9 presents the regimen for this treatment.

Table 9 VZV PEP dosages in people with normal renal function.

Drug	Dosage
Acyclovir	Children: 20 mg/kg/dose (maximum dose 800 mg) four times daily orally Adults: 800 mg five times per day orally for 7 days
Valacyclovir	Children: (for children ≥ 3 months of age)—20 mg/kg/dose (maximum dose 1 g) three times daily orally for 7 days Adults: 1 g three times per day orally for 7 days

Based on American Academy of Pediatrics (2018) Varicella-zoster virus infections. In: Kimberlin DW, Brady MT, Jackson MA, and Long SS (eds.) *Red Book: 2018 Report of the Committee on Infectious Diseases*, pp. 869–883. Ithaca: American Academy of Pediatrics.

Table 10 Estimated risk for acquisition of HIV from infected source, by exposure route (Patel et al., 2014).

<i>Exposure route</i>	<i>Type of exposure</i>	<i>Risk per 10,000 exposures</i>
Parenteral exposure	Blood transfusion	9250
	Needle-sharing injection drug use	63
	Percutaneous needle stick	23
Sexual	Receptive anal intercourse	138
	Insertive anal intercourse	11
	Receptive penile-vaginal intercourse	8
	Insertive penile-vaginal intercourse	4
	Receptive oral intercourse	Low
Other	Biting	Negligible
	Spitting	Negligible
	Throwing body fluids (including semen or saliva)	Negligible
	Sharing sex toys	Negligible

HIV infection postexposure prophylaxis

The risk of HIV transmission following accidental exposure varies depending on the type of exposure (Table 10).

Factors that can increase the risk of HIV transmission include sexually transmitted diseases, a high viral load in a source and acute and late-stage HIV disease, and devices visibly contaminated with a patient's blood. Factors that can decrease the risk are antiretroviral treatment, PrEP, condom use, and male circumcision (Jain and Mayer, 2014). None of these factors have been estimated in the Table 10.

Procedure proposed in occupational exposure to HIV

Occupational exposure to potential HIV-infected material is defined as job-related contact with potentially infectious blood, tissue, or body fluids in a manner that allows for possible transmission of HIV. Therefore, this situation requires consideration of PEP (Joyce et al., 2015) (Table 11).

The management of health care personnel (HCP) after a significant exposure to HIV-positive patient blood or body fluid should aim immediately to reduce the probability of transmission. All medical institutions should have readily available recommendations for such a situation. The initial actions after HCP exposure is immediate cleansing of the exposed site. For skin exposures, the contaminated area should be cleaned with soap and water. For mucous membranes, the exposed place should be flushed with the more amount of water. Eyes should be cleaned with saline or water. Squeezing the wound is not recommended (CDC, 2002a,b).

The recommended HIV-exposure chemoprophylaxis is a three-drug regimen that is given to HCP with occupational exposure to potential HIV-infected material. Indications for implementation of PEP are: exposure to body fluids from a person with confirmed HIV infection or from a source currently tested for HIV, especially if the person is from the group at increased risk of HIV infection or shows potential symptoms of HIV infection. If it is not possible to perform source testing, PEP is considered, however, direct indications depend on the individual case of exposure assessment. In each case, the decision to implement PEP should be based on the analysis of the risk of infection, the toxicity of the proposed procedure for HCT, and their individual preferences (Kuhar et al., 2013).

PEP to HCP should be started as soon as possible, preferably within the first 2 h of the incident. It is not recommended to introduce PEP after 72 h because of reduced effectiveness. Recommendations of some countries allow for delayed implementation of PEP to HCP, however, they refer to individually considered cases and concern only extremely massive exposures (Kuhar et al., 2013). The recommended duration of PEP is 4 weeks; shorter courses in primate studies were less effective (Table 12).

HIV-PEP in nonoccupational expositions

After a possible exposure to HIV infection, individuals should be evaluated if the nonoccupational PEP with antiretroviral therapy should be offered to reduce the risk of viral transmission. The data evaluating nonoccupational PEP are limited, but feasibility and safety data have led to widespread acceptance of this practice (Kuhar et al., 2013). People who in the last 72 h have been subjected high-risk exposures like accidental percutaneous exposure to potentially infected blood and unprotected sexual intercourse with an

Table 11 Division of body fluids depending on the risk of HIV infection (Panlilio et al., 2005).

<i>Body fluids implicated in the transmission of HIV</i>	<i>Potentially infectious body fluids (undetermined risk for transmitting HIV)</i>	<i>Fluids that are not considered infectious unless they contain blood include</i>
Blood, semen, vaginal secretions, other body fluids contaminated with visible blood.	Cerebrospinal, synovial, pleural, peritoneal, pericardial, amniotic fluids	Feces, nasal secretions, saliva, gastric secretions, sputum, sweat, tears, urine, vomitus.

Table 12 Selection of antiretroviral therapy for 28-day regimens for HCP PEP (WHO, 2016a,b).

HCP group	Preferred/ alternative	Drugs	
Adults, with normal renal function (creatinine clearance ≥ 60 mL/min)	Preferred	Tenofovir disoproxil fumarate-emtricitabine (300/200 mg once daily) plus dolutegravir (50 mg once daily)	!Not recommended for pregnant women or all persons who are able to become pregnant, due to the risk of neural tube defects. ^a The risk of a fetus developing a neural tube defect is during the first 28 days. Ritonavir is used in clinical practice as a pharmacokinetic enhancer to increase the trough concentration and prolong the half-life of darunavir. It is not counted as a drug directly active against HIV regimens.
	Alternative	Tenofovir disoproxil fumarate-emtricitabine (300/200 mg once daily) plus raltegravir (400 mg twice daily) Tenofovir disoproxil fumarate-emtricitabine (300/200 mg once daily) plus darunavir (800 mg once daily) and ritonavir (100 mg once daily)	
Adults with renal dysfunction (creatinine clearance ≤ 59 mL/min)	Preferred	Zidovudine and lamivudine, with both doses adjusted to degree of renal function plus raltegravir (400 mg twice daily) or dolutegravir (50 mg once daily) Zidovudine and lamivudine, with both doses adjusted to degree of renal function plus dolutegravir (50 mg once daily)	
	Alternative	Zidovudine and lamivudine, with both doses adjusted to degree of renal function plus darunavir (800 mg once daily) and ritonavir (100 mg once daily)	

^aUS FDA. Juluca, Tivicay, Triumeq (dolutegravir): FDA to Evaluate - Potential Risk of Neural Tube Birth Defects <https://www.fda.gov/safety/medwatch/safetyinformation/safetyalertsforhumanmedicalproducts/ucm608168.htm> (Accessed on May 21, 2018).

HIV-infected person are eligible for prophylaxis. The selection of drugs for prophylaxis in adults is analogous to the exposure to HCP (Morbidity and Mortality Weekly Report, 2016; WHO, 2016a,b).

Postexposure vaccinations

Preexposure childhood and adolescent immunizations are some of the most effective methods of preventing serious illness. However, there are medical situations in which postexposure use of a vaccine reduces the incidence of a given disease or modulates its course. Postexposure vaccinations are used in the prevention of the following diseases: diphtheria, tetanus, rabies, measles, chicken pox, hepatitis A, and hepatitis B. In certain situations, apart from PEP vaccination, an appropriate immunoglobulin preparation (active-passive immunoprophylaxis) is administered; in the case of contraindications to vaccination, only immunoglobulin preparation (passive immunoprophylaxis) is used.

Tetanus

People can be exposed to tetanus via wounds and animal bites. The indications for postexposure tetanus vaccination are based on the individual's immune status (established based on medical records, not the collected history) and the individual's infection risk assessment. The risk of infection depends on the type of wound and the circumstances of the injury; it is low in the case of fresh, slightly contaminated wounds, without necrotic tissues, and high in the case of extensive, old wounds (surgically prepared >24 h from the wound) or heavily contaminated wounds containing necrotic, crushed, stabbed, and gunshot tissue (Havers et al., 2020).

Proposed procedure and regimen

Indications for PEP vaccination against tetanus (low or high risk of infection) (Liang et al., 2018):

- no tetanus vaccinations, incomplete vaccination, vaccination history unknown/uncertain—3 doses of vaccine at 0, 1, and 6 months;
- last dose of tetanus vaccine (basic or booster immunization) given more than >10 years ago in clean, minor wounds and >5 years ago for all other wounds—1 dose of vaccine.
- in a person who had received the last dose of tetanus vaccine <5 years ago, there is no indication for postexposure vaccination if there is a low risk of infection, If there is a high risk of infection, administration of a single dose of the vaccine may be considered.

In the people with high-risk wounds who are qualified for PEP, simultaneous administration of the vaccine and immunoglobulin should be considered (Liang et al., 2018).

Diphtheria

Vaccinations against diphtheria are part of the routine prophylaxis in children and according to the recommendations of some countries, they should be supplemented in adults. In practice, often at the time of contact with the disease, it turns out that the documentation regarding vaccinations is incomplete or that the person had not continued to vaccinate (Roses and Bonvehí, 2019). PEP vaccinations can be dedicated to people who had close contact with diphtheria patients and incomplete/unknown vaccination history or the last dose of vaccine given >5 years ago. A close contact is defined as person-to-person contact through respiratory droplets coming from diphtheria source or exposure to infected skin lesions and articles soiled with discharges from these lesions (Bader and McKinsey, 2013).

Proposed procedure

After close contact with a symptomatic and asymptomatic case of diphtheria, the exposed person should get either tetanus-diphtheria (Td) or tetanus-diphtheria-pertussis (Tdap) vaccine if no documentation of receipt of a three-dose primary immunization series, or if the last dose of vaccine was given >5 years ago (Liang et al., 2018).

Regimen

There is currently no monovalent vaccine against diphtheria available; all applied vaccinations are combined. The choice of vaccine depends on the age of the exposed person. In children <7 years of age, the diphtheria-tetanus-acellular pertussis (DTaP) vaccine is recommended as the part of routine childhood vaccination. In adolescents and adults, it is preferred to use Tdap in people who never got Tdap or whose status is unknown. In patients who got Tdap, a Td booster is given every 10 years (Havers et al., 2020).

Rabies

Postexposure vaccination against rabies applies to people who have had contact with an animal that is sick or suspected to be suffering from rabies (Table 13). Vaccination may be administered alone or in combination with specific immunoglobulin depending on the circumstances of the event that represents the risk of infection and condition of the animal. Consultation with the local public health agency can be valuable in assessing the risk of transmission after a potential exposure (WHO, 2021).

Proposed procedure

PEP should be administered immediately after a rabies exposure. The possible moment of occurrence of rabies symptoms is considered the limit of prophylaxis administration. On average, the symptoms of the disease appear about 45 days after exposure, although cases with a much longer incubation period, up to 8 years, have been recorded. In certain medical situations, the vaccination may be postponed until rabies is confirmed in the animal. These are:

- testing in case rabies is suspected;
- post-mortem examination of a dead animal;
- conducting a 15-day veterinary observation of the animal—only in the case of a dog or a cat (WHO, 2021).

Regimen

WHO (2021; Rupprecht et al., 2010) currently only recommends the use of purified cell-culture and embryonated egg-based rabies vaccines (Table 14).

Table 13 Categories of rabies exposure and PEP (WHO, 2021).

	Exposure	PEP
Category I	Touching or feeding an animal or licks on intact skin	Not indicated
Category II	Nibbling of uncovered skin, minor scratches or abrasions without bleeding: exposure	Only vaccine
Category III	Single or multiple transdermal bites or scratches, contamination of mucous membranes with saliva from licks, licks on broken skin, exposure due to direct contact with bats: severe exposure	Vaccine and specific immunoglobulin

Table 14 Rabies vaccine dosage.

Vaccination category	Vaccine	Days
Not previously vaccinated	Human diploid cell vaccine (HDCV) or purified chick embryo cell vaccine (PCECV) 1 mL, IM (deltoid area)	0, 3, 7, 14, (28—the fifth dose is used for the person with immunosuppression)
Previously vaccinated		0, 3–7

Adapted from Rupprecht CE, Briggs D, Brown CM, et al. (2010) Use of a reduced (4-dose) vaccine schedule for postexposure prophylaxis to prevent human rabies: Recommendations of the advisory committee on immunization practices. *MMWR - Recommendations and Reports* 59: 1–8; World Health Organization (2021) *Vaccinations and Immunization*. <https://www.who.int/teams/control-of-neglected-tropical-diseases/rabies/vaccinations-and-immunization>.

If rabies is ruled out after tests or 15-day observation, the exposed person is released from prophylaxis. If it has started, the prophylaxis is stopped. Currently, the biggest problem in many countries is the lack of availability of the rabies vaccine, and in the case of developing countries, price is the biggest issue (Fisher and Schnell, 2018).

Measles

PEP in the case of close contact with measles should cover only people who have not been given (or do not have documentation of two vaccinations) against measles. Such people should be offered the combined measles-mumps-rubella (MMR) vaccination as soon as possible (unless there are absolute contraindications). There is currently no monovalent vaccination available.

Proposed procedure

Prophylactic administration of the vaccine within 72 h of exposure to measles is considered to be the most effective approach. However, vaccination should be offered at any interval following exposure in order to offer protection from future exposures. MMR vaccination is highly effective in primary prevention of measles, with a two-dose vaccine effectiveness of 99%. Nevertheless, the exposed person should be advised to self-monitor for potential measles symptoms (Rice et al., 2004).

Varicella-zoster virus

Varicella vaccine should be administered postexposure to individuals who lack evidence of immunity to varicella, have no varicella vaccine contraindications, and are >12 months of age, including adults. Exposure is defined as face-to-face contact with an infectious person while indoors. The duration of close contact is not certain, however, it should not be transient. Certain experts suggest a contact of >5 min as constituting significant exposure (American Academy of Pediatrics, 2018e).

Proposed procedure

According to ACIP recommendations, after the VZV exposition, a qualified person should get VZV vaccine ideally within 3–5 days after the person is exposed. This may prevent varicella or make it less severe. Even if it has been more than 5 days, the vaccine should still be offered, especially to people in an environment at risk of an epidemic (Marin et al., 2007).

Passive postexposure prophylaxis

Passive PEP can be considered when vaccines for active immunization are contraindicated (pregnancy, small infants) or unavailable and in some specific situations when unimmunized individuals have been exposed to the highly infectious agent and require immediate protection. Passive immunization may also have a role in the management of immunocompromised people unable to respond adequately to a vaccine. The duration of the beneficial effects provided by passive immunizing agents is relatively short-lived and protection may be incomplete.

Both types of IgG preparations available are used in PEP. Most immunoglobulins must be injected intramuscularly (IMIG), although an intravenous (IVIG) preparation is also available. The proposed procedures depending on the type of pathogen are presented in Table 15.

Table 15 Passive postexposure prophylaxis depending on the type of pathogen.

Disease	Dosage	Patient groups	Timing
Polyvalent immunoglobulins			
Hepatitis A (Nelson et al., 2018; Link-Gelles et al., 2018)	IMIG—0.02–0.1 mL/kg im.	Immunoglobulin can be considered for people who were exposed to HAV and were not vaccinated before or were not infected by HAV. Risk groups include: – Household and sexual contacts of persons with hepatitis A, – Newborn infants of HAV-infected mothers, – Staff and children at child-care centers and schools with HAV outbreaks; – Staff of custodial care institutions with HAV outbreaks, and individuals exposed to HAV through food or waterborne outbreak (according local indications). Target IMIG-PEP group: (1) Only IMIG: Children <12 months, patients in immunosuppression and with contraindications to preventive vaccinations. (2) Vaccination with IMIG: people > 40 years of age (in Great Britain and Canada > 50–60 years of age), patients with chronic liver diseases.	Up to 14 days from contact with the HAV-infected person

Table 15 (Continued)

Measles (McLean et al., 2013; American Academy of Pediatrics, 2018c)	IMIG 0.5 mL/kg bw. (maximum dose 15 mL) or intravenous immunoglobulin (IVIG) 400 mg/kg	Administration of immunoglobulins is indicated for PEP of measles in: – Infants (vaccination may be considered at the age of 6–12 months); – Pregnant women with undocumented immunity; – People with severe immunodeficiencies: primary, after bone marrow transplant (at least up to 12 months after the end of immunosuppressive treatment or longer if the graft versus disease is developed), people with acute lymphoblastic leukemias (up to 6 months after the end of chemotherapy) and patients diagnosed with AIDS or HIV with severely immunodeficiency ($CD4 < 15\%$ or $CD4 < 200/mm^3$) or not vaccinated with MMR vaccine after receiving effective antiretroviral therapy.	Immunoglobulins can be used up to 6 days after contact with the patient
Rubella (McLean et al., 2013; Young, 2019)	IMIG—the dose: 20 mL (check local guidelines)	Administration of IMIG/IGIG can be considered for non-immune women with documented exposure to rubella during the first trimester (3 months) of pregnancy where termination is unacceptable or not an option (recommendations depends on local guidelines). !!!Passive immunization with IG is not effective in preventing rubella. Immunoglobulins given after exposure to rubella may modify or suppress symptoms but may not prevent infection, including congenital infection.	72 h from exposure
Hyperimmune immunoglobulins			
CMV infection (Rea et al., 2016; Kagan et al., 2019).	CMVIG-human CMV immunoglobulin intravenous	Actually using CMVIG in many previous indications were limited by antiviral medications. Only some experts consider using CMVIGG: – In concomitant with antiviral medications in kidney, lung, liver, pancreas, and heart transplants from CMV seropositive donors to CMV seronegative recipients; – In prevention of maternal-fetal transmission of CMV after primary maternal infection during pregnancy (off-label indication).	Repeated infusion depended on indications.
Hepatitis B (Terrault et al., 2018)	HBIG—human hepatitis B immunoglobulin	HBIG should be administered after: – Acute exposure to blood, plasma or serum containing HBsAg (parental exposure, mucous membrane contact or oral ingestion); – Perinatal exposure of infants born to HBsAg-positive mothers; – Sexual exposure to HBsAg-positive persons; – Household exposure to persons with acute HBV infection. Target PEP groups: – Unvaccinated or incomplete vaccinated patients; – Documented nonresponder after 2 complete vaccination; – Newborns of HBsAg-positive mothers—one dose of HBIG with the first dose of the hepatitis B vaccine series.	Most (94.9%) infants born to infected women receive recommended prophylaxis within 12 h of birth.
Rabies (American Academy of Pediatrics, 2018; Pattanaik and Mani, 2019)	Rabies immune globulin (human) (HRIG) always administered as part of rabies vaccine regimen. Only local wound infiltration/IM: 20 units/kg in a single dose.	Patients in IIIth risk category: single or multiple transdermal bites or scratches, contamination of mucous membranes with saliva from licks, licks on broken skin, exposure due to direct contact with bats: severe exposure.	HRIG should be administered as soon as possible after exposure, preferably at time of first rabies vaccine (day 0) dose but if the vaccine was started without HRIG, it can be given through the 7th day after the day 0. HRIG is not recommended after the 7th day.
Tetanus (Havers et al., 2020; Callison and Nguyen, 2020)	Human tetanus immune globulin (HTIG) 250 units IM	Patients with the high risk wounds (especially wounds contaminated with dirt, feces, soil, or saliva; puncture wounds; avulsions; or wounds resulting from missiles, crushing, burns, or frostbite): – Who have received fewer than three doses of tetanus toxoid;	HTIG can be given up to 21 days for unvaccinated individuals if indicated

(Continued)

Table 15 (Continued)

Varicella (CDC, 2013; Levin et al., 2019; Gans and Chemaly, 2021)	A purified human VZV immune globulin (VarizIG).	– Whose immunization status is uncertain. Patients without evidence of immunity to varicella who are at high risk for severe varicella and complications, who have been exposed to varicella or herpes zoster, and for whom varicella vaccine is contraindicated, should receive VarizIG. Patient groups recommended by CDC to receive VarizIG include the following: • Immunocompromised patients without evidence of immunity. • Newborn infants whose mothers have signs and symptoms of varicella around the time of delivery (i.e., 5 days before to 2 days after). • Hospitalized premature infants born at ≥ 28 weeks of gestation whose mothers do not have evidence of immunity to varicella. • Hospitalized premature infants born at < 28 weeks of gestation or who weigh ≤ 1000 g at birth, regardless of their mothers' evidence of immunity to varicella. • Pregnant women without evidence of immunity.	Candidates for VarizIG should receive it as soon as possible and within 10 days of exposure

Disinfectants are of great importance for controlling the microbial population in healthcare facilities and within cleanrooms (Sandle, 2012a). However, the selection of the most appropriate disinfectants to use is not straightforward and different key criteria need to be considered for the selection of disinfectants, appropriate to the given application. Whilst selection is important, disinfectants must also be applied and used appropriately. Given that the objective of the disinfectant is to kill microorganisms and to reduce the surface bioburden then the real test of whether a disinfectant is efficacious, is with the numbers of microorganisms present. Disinfectants are required to undergo efficacy testing, both in suspension and on a range of surfaces (Vina et al., 2011). Ongoing assessments of continued suitability is through periodic viable microbiological environmental monitoring using surface techniques like contact plates and swabs. Further evidence as to how effective a disinfectant is can be shown with the types of microorganisms recovered (the “microflora”) (Sandle, 2011).

The term disinfection is normally applied to an inanimate object (sometimes the term biocide is used, although this relates to a larger group of chemical agents). The term antiseptic is used to describe the reduction of a microbial population on living tissue. Thus, an antiseptic is a disinfectant which can safely be applied to the surface of the skin (sometimes the terms “hand sanitizer” or “hand disinfectant” are used interchangeably.) In turn, the term disinfectant is usually reserved for liquid chemical germicides which cannot be applied to tissues because of their corrosive or toxic nature.

Disinfectants vary in their spectrum of activity, modes of action and efficacy. Some are bacteriostatic, where the ability of the bacterial population to grow is halted. Here the disinfectant can cause selective and reversible changes to cells by interacting with nucleic acids, inhibiting enzymes or permeating into the cell wall. Other disinfectants are bactericidal in that they destroy bacterial cells through different mechanisms including causing structural damage to the cell; autolysis; cell lysis and the leakage or coagulation of cytoplasm (Price, 1995). Within these groupings the spectrum of activity varies with some disinfectants being effective against vegetative Gram positive and Gram-negative micro-organisms only while others are effective against fungi. Some disinfectants are sporicidal in that they can cause the destruction of endospore forming bacteria (these are the most difficult forms of microorganisms to eliminate from cleanroom surfaces) (Russell, 1995).

Microbial kill mechanisms

With a bacterial cell there is a common sequence of events whereby the disinfectant interact with the cell surface; this is followed by penetration into the cell and action at the target site(s) (Brown and Gilbert, 1993). Different disinfectants attack bacterial cells in different ways; and, conversely, different species of microorganisms vary in their resistance to different disinfectants. These can be affected by the population of microorganisms present, their species, and the community with which they are bound. Many disinfectants are effective against fungi although, like bacteria, the cell wall chemistry and internal cellular structure differ. Thus, fungal susceptibility to disinfectants differs. To add to this, susceptibility also relates to the physiological state and stage of growth. Hence a disinfectant effective against a target preparation of bacteria may or may not be effective against fungi (Vijayakumar et al., 2012). In addition, disinfectants used in the pharmaceutical industry may need to demonstrate virucidal properties. In certain sectors, like biotechnology, this is a concern. Here non-enveloped viruses tend to be more resistant than enveloped forms (Rabenau et al., 2014).

One important determinant is with the numbers of organisms. An disinfection agent is considerably more effective against a low number of microorganisms than a higher number or a population with a greater cell density. Similarly, a disinfectant is more effective against a pure population than mixed population of microorganisms. Use of a routine disinfectant will not be likely to kill all microorganisms present and a number will remain viable. Whether the surviving microorganisms multiply in sufficient number is dependent upon the condition in which the surviving population remains, the available nutrients, and the time between repeat applications of the disinfectant.

Following from numbers, different types of microorganisms have varying levels of resistance to broad spectrum disinfectants. This can be represented by the “classic” hierarchy of resistance, as shown in Fig. 1 below (Russell, 1986). The increased resistance is primarily due to the cell membrane composition or type of protein coat.

Resistance is acquired through natural genetic properties of the microorganisms or it is acquired through phenotypic or genotypic variations (similar to antibiotic resistance through the over-use of one type of disinfectant). Generally, innate sensitivity results in Gram-negative bacteria being more resistant to disinfectant applications than Gram-positive bacteria (Otter et al., 2015). The reason for the increased resistance among Gram-negative bacteria can be attributed to a greater abundance of a hydrophobic lipopolysaccharides (LPS) in the cell membrane, whereas the Gram-positive membrane is primarily made up of inelastic “murein sacculi.” It is interesting that within the group of least resistant, Gram-positive bacteria, there are microorganisms (e.g., *Bacillus*, *Clostridium*, etc.) that can produce endospores which are the several degrees more resistant than their vegetative counterpart. This may be because of the relative impermeability of the polypeptides which make up the spore coat to hydrophilic agents. The bacterial spore is made up of three layers (Pommerville, 2014):

- Spore coat—which acts as a sieve to excluded toxic substances from the environment.
- Spore cortex—a protective structure made up of peptidoglycan.
- Core wall—the structure that surrounds the protoplast or core of the endospore.
- Core—the spore chromosomal DNA, encased in chromatin-like proteins called small acid-soluble spore proteins. These proteins protect the spore DNA. The core contains cell structures like ribosomes and other enzymes. These are not metabolically active.

Sometimes the spore coat is surrounded by a thinner structure call the exosporium (for example, with an organism like *Bacillus cereus*). The exosporium is the portion of the spore that interacts with the environment or host organism, and may contain spore antigens (Redmond, 2004).

A final factor shaping resistance is with the location of the organisms. The location of microorganisms can influence the effectiveness of a disinfectant. Microorganisms in suspension are easier to kill than those affixed to surfaces. This is due to the mechanisms of microorganism attachment, such as bacteria fixing themselves using fimbriae or when a biofilm community develops (8). Such positioning impacts the contact time required for the disinfectant to bind to the microorganism, cross the cell wall and act at the target site.

Fig. 1 Pyramid of resistance to common disinfectants. Adapted from Russell AD (1986) Mechanisms of resistance to antiseptics, disinfectants and preservatives. *Pharmacy International* 7: 305–308.

Classifying disinfectants

There are several ways to categorize the different types of disinfectants available. One common way is to distinguish between non-oxidizing disinfectants (such as alcohol) and oxidizing disinfectants (halogens like iodine, peracetic acid and chlorine dioxide). Non-oxidizing disinfectants do not have sporicidal action, whereas several oxidizing disinfectants are effective sporicides.

Common non-sporicidal disinfectants

The majority of disinfectants outlined below have a specific mode of action against microorganisms and generally have a lower spectrum of activity compared to oxidizing disinfectants. The list is far from absolute; the intention is to describe the more common types of disinfectants found within the pharmaceutical or healthcare setting.

Alcohols

Alcohols have an antibacterial action against vegetative cells. The effectiveness of alcohols against vegetative bacteria increases with their molecular weight (i.e., ethanol is more effective than methanol and in turn isopropyl alcohols are more effective than ethanol). Alcohols, where efficacy is increased with the presence of water, act on the bacterial cell wall by making it permeable. This can result in cytoplasm leakage, denaturation of protein and eventual cell lysis (alcohols are one of the so called “membrane disrupters”). The advantages of using alcohols include a relatively low cost, little odor and quick evaporation. However, alcohols have very poor action against bacterial and fungal spores and can only inhibit spore germination at best (McDonnell and Russell, 1999).

Aldehydes

Formaldehyde and glutaraldehyde are common to the aldehydes. Glutaraldehyde is a very effective disinfectant (and sterilant), has a wide spectrum of activity, and is effective against bacterial and fungal spores. However, glutaraldehyde is little used today due to personnel health and safety concerns. Formaldehyde and *o*-phthalaldehyde are slightly less effective in comparison due to a slower rate of reaction but possesses an equally wide spectrum of activity. Aldehydes have a non-specific effect in the denaturing of bacterial cell proteins and can cause coagulation of cellular protein (Angelillo et al., 1998).

Amphoterics

Amphoterics are acidic and have a relative wide spectrum of activity but are limited by their ability to damage bacterial endospores. An example is alkyl di(aminoethyl) glycine or derivatives (Ernst et al., 2006).

Acid anionics

Acid anionics are weak acids with a relatively limited spectrum of activity and are very pH dependent. An example of this group is carboxylic acid. They are not effective against fungi or spore forming bacteria. Their bactericidal properties arise from their ability to cause cell disruption through proton motive force where the balance of hydrogen across the cell is disrupted which can affect cellular division by disruption of oxidative phosphorylation (Antony and Jayakannan, 2007).

Biguanides

Biguanides are polymers supplied in salt form, such as chlorhexidine, alexidine and hydrochloride. Biguanides have a relatively wide spectrum of activity with the exception of killing bacterial endospores. This group is most effective at an alkaline pH and is rarely effective under acidic conditions. Biguanides affect the bacterial cell membrane and enter the cell through diffusion causing cell disruption and cytoplasm leakage (Wilson et al., 1991).

Phenolics

Phenols are produced from the fractionation of tar and are among the oldest scientifically evaluated disinfectants, dating back to Robert Koch's evaluation of phenol's bactericidal effect against *Bacillus anthracis*. The commonly used phenolic is basic phenol (carbolic acid) although synthetic variants are widely used. Phenol can be made more complex by the addition of halogens such as chlorine (the bis-phenols and halophenols) to make compounds like triclosan and chloroxylenol. Phenols are bactericidal and antifungal but are not effective against bacterial spores. Some phenols cause bacterial cell disruption through proton motive force while others attack the cell wall and cause leakage of cellular components and protein denaturation (Bergan and Lystad, 1972).

Quaternary ammonium compounds (QACs)

QACs are cationic salts of organically substituted ammonium compounds and have a fairly broad range of activity against microorganisms, although more effective against Gram-positive bacteria at lower concentrations than Gram-negative bacteria. They are considerably less effective against bacterial spores. QACs are sometimes classified as surfactants. An example is benzalkonium chloride (18). QACs are the most widely used of the non-oxidizing disinfectants in the pharmaceutical industry. Their mode of action is on the cell membrane which leads to cytoplasm leakage and cytoplasm coagulation through interaction with phospholipids (Vijayakumar et al., 2012).

Sporicidal disinfectants

Some disinfectants are sporicidal in that they can cause the destruction of endospore forming bacteria (these are the most difficult forms of microorganisms to eliminate from cleanroom surfaces). Endospores are the most resistant because of the relative impermeability of the polypeptides, which make up the spore-coat, to hydrophilic agents (Sandle, 2012a). It is important to note, however, that a chemical agent does not have to be sporicidal in order to be classified as a “disinfectant.”

Bacterial spores present a problem in cleanrooms due to the mechanisms which allow bacteria to survive for long periods in low nutrient conditions. Bacteria which form spores include species like *Bacillus*. If a disinfectant is not effective against spores, the risk is that the bacteria will return to the vegetative state at some point and pose a contamination risk (McDonnell and Russell, 1999).

Hypochlorous acid

This is a weak acid with the chemical formula HOCl. It forms when chlorine dissolves in water, and it is the HOCl moiety that actually does the disinfection. The chemical elicits its bactericidal activity by acting on a wide variety of biomolecules, including DNA, RNA, fatty acid groups, cholesterol and proteins.

Sodium dichloroisocyanurate (NaDCC)

Sodium dichloroisocyanurate is a chemical compound widely used as a cleansing agent and disinfectant; this salt is an active ingredient in many bleaches.

Chloramines

Chloramines are derivatives of ammonia. They are produced by chlorine gas or hypochlorite being added to the water to produce hypochlorous acid. Following this, ammonia is added to the water to react with the hypochlorous acid and produce a chloramine. Although these chemicals are beginning to be used in cleanrooms, they are more often used as a water treatment (such as for swimming pools). There is some discussion about the chemicals being implicated as mutagens.

Chlorine dioxide

This is a chemical compound with the formula ClO_2 . As one of several oxides of chlorine, it is a potent and useful oxidizing agent. This oxidizing agent requires combination of a base (organic acid, like lactic acid) and an activator (sodium chlorite) to come together to elicit the production of free chlorine. In general, this chemical retains active chlorine for longer than hypochlorite and it seemingly has a longer lasting bactericidal effect. However, it has been known to have stability issues and the shelf-life, once the two component chemicals come together, is variable (Sandle, 2016a).

Hypochlorites

Hypochlorite is a compound of chlorine and oxygen, with a chemical formula ClO^- , which can combine with a number of counter ions such as Na^+ (household bleach) and Ca^+ (used for water treatment) ions, to form the corresponding hypochlorites.

Hydrogen peroxide (H_2O_2)

Hydrogen peroxide is a colorless liquid that is the simplest peroxide (a compound with an oxygen-oxygen bond). It is used as a strong oxidizer, bleaching agent and disinfectant. Hydrogen peroxide is an effective sporicide which produces destructive hydroxyl free radicals. Like peracetic acid it has a wide spectrum of activity and it is relatively rapid (although the relationship between concentration and time needs to be carefully assessed). As with peracetic acid there are safety concerns, and it can be more affected by the presence of interfering substances on surfaces.

Peracetic acid

Peracetic acid (sometimes called peroxyacetic acid) based disinfectants are prepared from peracetic acid (the active ingredient), which is formed from hydrogen peroxide and acetic acid in solution. The peracetic acid results from a reaction between hydrogen peroxide and acetic acid. Preparations of peracetic acid are usually produced in concentrations of 5–15% (Denyer and Stewart, 1998).

Peracetic acid functions as a disinfectant by oxidizing the outer cell membranes of microorganisms. The oxidation mechanism consists of electron transfer. This causes the microorganism to be rapidly deactivated as the acid penetrates the polypeptide spore coat and then damages the macromolecules like carbohydrates, nucleic acids and lipids within the cell, ultimately leading to cell lysis and microbial cell death.

Some manufacturers produce a hydrogen peroxide/peracetic acid blend. This is commonly a formulation made up of less than 10% acetic acid with small amounts of hydrogen peroxide and peracetic acid. With the blend, arguably peracetic acid is the more potent; however, hydrogen peroxide is less damaging to surfaces (and to environment).

Selecting between disinfectants

Some considerations for selecting different disinfectants include:

- The disinfectant must be rapid in action with an ideal contact time of less than 10 min (the longer the contact time, then the longer the surface needs to be left after application and prior to use.)
- Some disinfectants require certain temperature and pH ranges in order to function correctly. One type of disinfectant, for example, may not be effective in cleanroom which is set at a cold temperature (below 10 °C) and many disinfectants have not been validated by the vendor to show that they work at temperatures below 20 °C.
- For use in higher-grade cleanrooms—ISO class 5 and 7 areas (EU GMP Grade A and B cleanrooms)—the disinfectant must be supplied irradiated or be able to pass through a sterilizing grade filter (through a 0.2 µm filter) without loss of its germicidal properties, or be provided sterile and ready-to-use (with sterility achieved through a process like gamma irradiation).
- The disinfectant must be compatible with the detergent used for the first “clean” (this is because residues from some detergents can inactivate the “active” ingredient in some disinfectants).
- Some disinfectants leave residues on surfaces. Whilst this can mean a continuation of an antimicrobial activity, residues can also lead to sticky surfaces and or the inactivation of other disinfectants.
- The disinfectant should be relatively safe to use. Here the main concern is with operator welfare. A related concern is the impact upon the environment, especially in the way that waste disinfectant solutions are disposed of.
- Different disinfectants are not compatible with all types of surfaces. The disinfectants should ideally not damage the materials (to which they are applied) by corrosion or discoloration. Certain sporicidal disinfectants, such as chlorine-based products, can corrode stainless steel unless residues are wiped away, such as with Water-for-Injection or a 70% alcohol solution.
- When using sporicidal disinfectants, one consideration is the presentation. Some sporicidal disinfectants require two components to be mixed together and the resultant combination often has a limited time within which it can be used due to the length of time that the main ingredient remains active. There are advantages in having some disinfectants available both in concentrate form, suitable for diluting, for cleaning large surface areas, and ready-prepared solutions, such as trigger sprays, for smaller areas.

Rotation of disinfectants

When cleanroom disinfectants are selected it is common practice to select two or more disinfectants. This is for several reasons (Sutton, 2008):

- Most disinfectants do not have a complete spectrum of activity effective against all microorganisms (spectrum of activity is the ability of the disinfectant to kill different types of microorganisms and microorganisms which are in different physiological states). The disinfectants commonly used are often effective against vegetative cells but are not sporicidal. To maintain an effective contamination, control the elimination of bacterial endospores through a sporicidal disinfectant is a recommended (these are sometimes referred to as “high-level disinfectants”).
- The disinfectants with the formulations which are effective against the greatest range of microorganisms are often expensive. With this, many manufacturers use a general broad-spectrum disinfectant daily or weekly with a sporicidal disinfectant used weekly or monthly (a decision often based on the results of microbiological environmental monitoring and the characterization of the isolated microorganisms).
- There are some expressed concerns, although not support by any major study, that genetically acquired disinfectant resistance might occur in a similar way to antimicrobial resistance. The theory runs that if disinfectants are rotated, the possibility of resistance occurring decreases.
- Some regulatory authorities, including the European Medicines Agency and the UK MHRA, require two disinfectants to be used in rotation which is a Good Manufacturing Practice requirement. The argument for rotating two disinfectants is to reduce the

possibility of resistant strains of microorganisms developing. Whilst the phenomenon of microbial resistance is an issue of major concern for antibiotics there are few data to support development of resistance to disinfectants. Nonetheless, it remains a regulatory expectation.

Disinfectant efficacy testing

There are different approaches that can be taken for disinfectant qualification ("efficacy testing"). To demonstrate the efficacy of a disinfectant it is necessary to conduct the following tests:

1. In-use-dilution tests.
2. Surface challenge tests.
3. A statistical comparison of the frequency of isolation and numbers of microorganisms isolated prior to and after the implementation of a new disinfectant.

With these different tests there are different national standards, with some differences in terms of methodology and acceptance criteria. Described here is a generalized approach.

Both suspension tests and surface tests are conducted under clean and 'dirty' conditions. Clean conditions are intended to cover applications where the surfaces can be cleaned sufficiently before the application of the disinfectant, whilst dirty conditions are intended to cover applications where cleaning prior to disinfection is not undertaken or cannot be relied upon to produce a clean surface. On this basis, the simulated dirty conditions are arguably more important. Suspension and surface tests are divided between tests for vegetative bacteria; test for fungi; and tests for bacterial spores (Tomasino and Hamilton, 2006).

An important choice is with the microorganisms that form the test panel. With typical organisms for a healthcare or pharmaceutical facility, the following bacteria are often used:

- *Staphylococcus aureus* (ATCC 6538)
- *Enterococcus hirae* (ATCC 10541)
- *Pseudomonas aeruginosa* (ATCC 15442)
- *Escherichia coli* (ATCC 10536)

And the following fungi:

- *Candida albicans* (ATCC 10231)
- *Aspergillus brasiliensis* (ATCC 16404)

With fungi it is recommended that fungal spores are used since the presence of hyphae and mycelia can prevent disinfectant from contacting and penetrating spore.

In addition, with bacteria and fungi, isolates from the area where the disinfectants are to be used are often added to the test panel (termed "environmental isolates").

To assess a sporicidal disinfectant, the following organism as a spore suspension is recommended:

- *Bacillus subtilis* (ATCC 6633)

Where virucidal properties are required:

- Adenovirus-5 and poliovirus

The in-use (or suspension test) involves taking the disinfectant, at the required concentration, and adding to it an interfering substance (to simulate practical conditions) together with a known concentration of a challenge microorganism (derived from an 18–24 h culture). The suspension is then held for the required contact time and at a defined temperature. Once this time has elapsed, a proportion of the challenged disinfectant is transferred to a tube containing a suitable neutralizer, which is intended to inactivate the disinfectant. Once sufficient time has been given for neutralization, microbial survivors are assessed by plating out or filtering the disinfectant-neutralizer solution using a microbial culture method (Sutton et al., 2002).

It is important that the neutralizer used has been tested in advance to show that it is not toxic to any microbial survivors. An approach from this was outlined by Sutton and colleagues. This involves calculating both neutralizer efficacy ratios, by comparing the recovery of identical inocula from the neutralizing solution in the presence, or the absence, of a 1:10 dilution of the biocide; and neutralizer toxicity ratios, which are determined between recovery of viable microorganisms incubated for a short period in peptone, and in the neutralizing medium without the biocide. An effective and non-toxic neutralizer was established by ratios of ≥ 0.75 .

Surface testing involves aliquoting onto a surface coupon a mix of the challenge organism and, where required, an interfering substance (such a protein, to simulate dirty conditions). The surface coupon will be fashioned from a representative surface in the cleanroom (here several different materials will require testing in order to show how the disinfectant performs). To this an amount of the test disinfectant is added. The solutions are left for the required contact time. Once the contact time has elapsed, the coupon is

transferred to a neutralizer solution. Then, as with the suspension test once sufficient time has been given for neutralization, microbial survivors are assessed by plating out or filtering the disinfectant-neutralizer solution using a microbial culture method. A possible array of surfaces to consider (this will be facility dependent) are:

- Stainless steel,
- Glass,
- Aluminum,
- Epoxy,
- Enamel,
- Acrylic,
- Mipolam,
- Vinyl,
- Hardwood,
- Plastic,
- Plexiglas,
- Chromium

With both suspension and surface testing, microbial kill is assessed through logarithmic reduction (as expressed to base 10). Log reductions are a relative concept and the log reduction obtained will be impacted by the starting inoculum.

The statistical comparison part is commonly referred to as a field trial (in situ testing). This tests how well the disinfectant performs (either solely or in conjunction with another disinfectant in rotation) in the actual area(s) where the disinfectant will be used. The assessment is through surface based environmental monitoring where microbial counts and species are assessed prior to and after the application of the disinfectant.

To run an effective field trial, a baseline is established prior to and then during implementation of the new regime using intensive environmental sampling. The effectiveness of the new disinfectant is assessed via a statistical evaluation of the environmental monitoring data before and after implementation of the new regime. The obtained results should be equivalent or better. Field trials aim to capture the variability of practical application that may affect microbial susceptibility and disinfectant efficacy. These factors include:

- Detergent residues;
- Soiling;
- Variations of microbial attachment;
- Organisms under different stress conditions;
- Temperature fluctuations;
- Differences in pH.

With the above three-step approach, some users elect to run in-use dilution tests (or suspension tests); others chose to conduct surface tests only; and some will conduct both.

The validation approach

An approach that can be adopted for the validation of disinfectants to be used within the cleanroom is (Sandle, 2012b):

1. Screening tests: These may be used to compare various disinfectants (or different concentrations of a disinfectant) when making the choice of which disinfectants to purchase. This is usually by suspension testing.
2. Surface challenge tests. This is the most important disinfectant efficacy test and, as discussed above, typically conducted using standard organisms and environmental isolates on cleanroom surfaces.
3. Qualification the environmental monitoring media for use in conjunction with chosen disinfectant (see below).
4. Field trial. The field trial is conducted after the laboratory-based assays have been completed. The field trials tests whether the selected disinfectant(s) work in practice. This is a study of organisms isolated (frequency and type) before and after implementation of a new cleaning and disinfection regime. A field trial can also help to set appropriate frequencies of disinfection and the interval between the rotation of two different disinfectants.

There are several important factors that require assessing through disinfectant validation. These are (Sandle, 2012c):

- (a) The concentration of the disinfectant. Many users will test the manufacturer's recommended concentration, which keeps this part more straightforward. However, if the user seeks to establish a concentration this needs to be added, including a minimum and maximum range. Setting the concentration is easier to establish through suspension tests.
- (b) The contact time. This is time needed for the required level of microbial kill (or inactivation) to be achieved. A disinfectant product may have different contact times depending on the target organisms (for example an extended contact time will probably be needed for sporicidal action). In setting contact times, it is important that these are practical; many standards set contact times that are unrealistically long. A second area with contact times is that needs to be factored in is the rate of drying. In the laboratory setting, disinfectants will dry more slowly than in the cleanroom (where the air change rates are faster and the air is most likely to be less humid).

- (c) The microbial challenge. Many disinfectant efficacy standards use very high challenges (up to 1 million microbial cells) and associated multi-step logarithmic reductions. These are far in excess of what would be found in a cleanroom. Lower challenges can be used, with justification. This can lead to more practical contact times, especially when assessing sporicidal agents. A two-log reduction, for example, of bacterial spores should be sufficient for most cleanrooms.

An argument for accepting a lower log-kill acceptance criteria can be based on (Sandle, 2019a):

- Disinfectants are less effective against the high numbers of organisms used during testing than against the low numbers expected in a cleanroom environment
 - Stressed environmental organisms are easier to kill than the cultures using in testing
 - In practical situations disinfectants are applied by wiping/mopping which physically removes organisms enhancing the “kill”.
- (d) The types of surfaces. For surface testing a range of surfaces need to be tested. This will include common surfaces like vinyl, acrylic, glass, and laminate. Moreover, the surface type and condition can have a significant impact on efficacy (with condition older or damaged surfaces can be more challenging).
- (e) The quality of water used to dilute the disinfectant concentrate. The water quality (potable, purified or Water-for-Injections) should be the same as used in the production facility.
- (f) The temperature of use. Laboratory studies are commonly conducted at 20–25 °C. This normally matches process conditions. However, consideration will need to be given if the disinfectant is intended to be used in cold rooms, for example, since these lower temperatures may affect disinfectant efficacy.

Additional testing

As well as the general tests described above, many users elect to conduct the following additional assessments:

- (a) Testing at the end of the shelf life of the product:
1. Either as the solution *per se*,
 2. or a solution in contact with either the synthetic or natural fiber wipe.
- (b) When a product is reconstituted:
1. just before use
 2. and at the end of its in-use shelf life

The reason for doing so particularly applies to sporicides, which are chemicals that are generally reactive oxidizing species. These chemicals are essentially unstable or reactive towards packaging or wipe materials.

In some cases, with the development of a novel agent, pre-studies may be performed for establishing the appropriate concentration. For this dilution methods can be used to establish the minimum inhibitory concentrations (MICs) of antimicrobial agents: these are the reference methods for antimicrobial susceptibility testing and are mainly used to establish the activity of a new agent, to confirm the susceptibility of microorganisms to the agent that give equivocal results in routine tests, and to determine the susceptibility on various microorganisms where routine tests may be unreliable (Vijayakumar et al., 2016). Other alternate procedures for assessing disinfectant effectiveness include flow cytometry (using cytofluorometry) (Akhmaltdinova et al., 2016).

Practical application

Ensuring that surfaces are regularly disinfected and that the numbers of bacteria present are kept to a minimum is of great importance for contamination control. However, disinfectants are only effective when used in conjunction with a detergent. This is because most disinfectants have poor cleaning ability and will not easily penetrate “soil” (dust, grease and dirt). So, surfaces must be rinsed frequently with a detergent and then disinfected at frequent intervals (Sandle, 2016b).

Application can be controlled through written cleaning and disinfectant protocols. Establishing a cleaning and disinfection protocol or standard operating procedure is an important step for a pharmaceutical or healthcare organization in its microbial control program. An established and effective protocol will ensure that risks to the patient, or manufactured product, are minimized. In drawing together a program, advice is available from regulatory authorities (through “current” GMP) and consideration should be given to aspects discussed in this chapter: compatibility of detergents and disinfectants, the need for rotation, methods for cleaning and the results of method validation. Ideally the program should be published within the organization and it is important the staff are given sufficient time to carry out each cleaning step.

The procedures should cover the following aspects (Sandle, 2019b):

- The type of detergents and disinfectants to be used (which are compatible);
- The frequency of rotation of disinfectants;
- A list of suitable cleaning materials;
- Cleaning techniques;
- Contact times;
- Rinsing;

- Frequency of cleaning and disinfection;
- Procedure for the transfer of cleaning agents and disinfectants into and out of clean areas (including the procedure for sterilization of disinfectants);
- Holding times for detergents and disinfectants (for how long, after preparation, can a detergent or disinfectant be used?).

Factors affecting disinfectant efficacy

There are different factors which affect how well a disinfectant may or may not work in the practical setting. These are:

- Type and quantity of the organism as this presents the specific level of challenge to the agent(s) and so the concentrations required.
- Amount of protein-based materials present as this tends to inactivate and absorb the disinfectant.
- Presence of other organic compounds and soaps (e.g., non-ionic surfactants) either in the solution or the surfaces, as these interact with certain disinfectants even neutralizing them. In certain combinations this could enhance the effect for example quaternary ammonium compounds. In order for a disinfectant to be effective it must come into contact with and be absorbed by the microbial cell. If substances, such as oil, dirt, paper or grease, act as a spatial barrier between the microbial cell and the disinfectant, the efficacy of the disinfectant will be adversely affected. The presence of such substances ("soil") halts disinfectant efficacy by either reacting with the disinfectant or creating a barrier for the disinfectant. This effect is increased if the surface itself has defects and crevices which limit disinfectant penetration.
- The solution will also be affected by other inherent characteristics namely pH, temperature, concentration and possible interactions between other agents and containers. Generally, temperature influences the rate of reaction ([Abdallah et al., 2015](#)). Most disinfectants are more effective and kill a population faster at higher temperatures although many disinfectants, due to practical considerations, are manufactured to be used at ambient. Some disinfectants, particularly oxidizing agents like peracetic acid, have an optimal temperature of 40–50 °C, and sporicidal agents like *o*-phthalaldehyde are more effective at temperatures elevated above ambient. Disinfectants which are sensitive to temperatures other than ambient are normally assessed through the use of a temperature coefficient, or Q10 (which relates the increase in activity to a 10 °C rise in temperature).
- The effect of pH is important because it influences the ionic binding of a disinfectant to a bacterial cell wall thereby ensuring disinfectant molecules bind to a high number of microorganisms. Many disinfectants are more stable at a set pH range, for example, acid-based disinfectants can become less potent in alkaline conditions whereas a glutaraldehyde is more potent at a basic pH. The use of a disinfectant outside of its desired pH range results in reduced efficacy.

Environmental monitoring

The ultimate proof of sporicidal control is with the results of environmental monitoring, assessing surface count data. To assess the effectiveness of a sporicide in relation to contamination control, periodic environmental monitoring and trending of counts, incidences and isolates is required. If high recoveries of spore formers are noted, this should trigger a review of sporidical agents and practices. In addition, if spore forming microorganisms are found in the environment, consideration should be given to adding them to future disinfectant efficacy tests ([Sandle, 2019a](#)).

With environmental monitoring methods, care should be taken with the culture media selection and neutralizers. The neutralizers in the agar used for contact plates, for example, must have been examined to show they are effective against any residues from the sporicide that might remain on a surface.

Hand sanitization

Hand sanitization is of importance in healthcare and pharmaceutical settings. Personnel carry many types of microorganisms on their hands and such microorganisms can be readily transferred from person to person or from person to equipment or critical surfaces. Such microorganisms (including *Staphylococcus*, *Micrococcus* and *Propionibacterium*) are either present on the skin not multiplying (transient flora) or are multiplying microorganisms released from the skin (residential flora). For critical operations, some protection is afforded by wearing gloves. However, gloves are not suitable for all activities and gloves, if not regularly sanitized or if they are of an unsuitable design, will pick up and transfer contamination ([Larson, 1988](#)).

Hand sanitizers fall into two groups: alcohol based, which are more common, and non-alcohol based. The most commonly used alcohol-based hand sanitizers are Isopropyl alcohol or some form of denatured ethanol (such as Industrial Methylated Spirits), normally at a 70% concentration. The more common non-alcohol-based sanitizers contain either chlorhexidine or hexachlorophene. For hand sanitizers used on skin, these must not cause excessive drying and be non-irritating ([Rutala, 1995](#)).

Hand sanitizers should be applied to clean hands. For this, hands should be washed using soap and water for around 20 s. Handwashing removes around 99% of transient microorganisms (although it does not kill them). From then on, whether gloves are worn or not, regular hygienic hand disinfection should take place to eliminate any subsequent transient flora and to reduce the risk of the contamination arising from resident skin flora.

Personnel working in healthcare facilities and cleanrooms should be aware of the importance of hand sanitizers, the way in which they work, and the differences between them. This should be enforced through a rigorous training program and supervision. The understanding of staff as to why hygiene of gloved and ungloved hands is important, particularly when working near patients or with clean equipment, as employee attitude influences the hygiene and quality (Nicolle, 2007).

Introduction

Infectious diseases are one of the main causes of death throughout human history. Even in pandemics such as bubonic plague, infectious diseases were the primary cause of death and had reshaped civilization (Gould, 2016). When old written sources and archeological excavations are examined in detail, it is seen that societies had different methods of combating infections since ancient times. These methods could be the use of various herbs, honey, animal feces, and the topical application of moldy bread. Especially the fact that applying moldy bread is included in the sources of China, ancient Egypt, Rome, Serbia, and Greece shows how wide this practice has spread over geography (Keyes et al., 2008; Gould, 2016). On the other hand, the inclusion of sections on the benefits of molds in the book named “Theatrum Botanicum” published by John Parkinson in 1640 proves that molds were used in the treatment of infection thousands of years after ancient times.

The development of modern anti-infective agents as we know them today actually started in 1676 when Antonie van Leeuwenhoek discovered small living creatures, namely “animalcules,” with a microscope he designed (Karamanou et al., 2010). After this discovery, “bacteriology” and the relationship between bacteria-disease was studied. In addition to bacteria, fungus and malaria structures were also discovered in similar periods. On the other hand, with the geographical discoveries, it had become easier to transfer the knowledge from one point of the world to the different parts of the World (Finberg and Guharoy, 2012). For example, the use of cinchona bark for malaria treatment by indigenous peoples in South America was transmitted to Europe in the 17th century. Based on this knowledge, current anti-malarial drugs have been developed. Traditional Chinese medicine, which is based on the use of herbal medicines, still provides an idea for the development of new anti-infective drugs with its 5000-year history. A similar situation is valid for traditional Indian medicine.

The development of new drugs is a long and demanding process. Proper management of this process is crucial to the development of effective new anti-infective drugs and to accelerate the treatment of infectious diseases. Thanks to today's analysis possibilities, basic information about the effectiveness of a drug or drug delivery system can be obtained with *in vitro* methods without the need for *in vivo* or clinical studies.

The need for developing novel anti-infective agents and their pharmaceutical dosage forms

In the 20th century, the discovery of anti-infective agents had accelerated, and many new drugs have been introduced until today (Nathan, 2012). Obtaining synthetic or semi-synthetic anti-infective agents was initially achieved by imitating or improving the molecular structures of traditional drugs with known efficacy (Cos et al., 2006). With the scientific developments, as the biological structure of the pathogen is enlightened, new drug molecules with chemical groups that can directly interact with these structures have been synthesized. These new drugs, which are obtained by changes in chemical groups but their main molecular structure remains the same, are named “new generation.” Anti-infective agents are generally divided into four groups as anti-bacterial, anti-viral, anti-fungal, and anti-parasite. Anti-infective agents approved by FDA and EMA are available in different pharmaceutical dosage forms such as tablets, solutions, emulsions, suspensions, ointments, cremas, gels, and new drug delivery system (EMA, 2021; FDA, 2021).

Along with scientific developments, important steps have been taken in the treatment of anti-infective diseases with the use of many different agents. In addition, the importance of preventive medicine and the increase of community immunity thanks to

vaccines have also been significant steps in the prevention of infectious diseases. Improving the perception of hygiene and improvement of nutritional conditions have also been the other supportive components of the fight against infectious diseases (Cheng et al., 2003). Based on these four elements, a great fortress was built against infectious diseases as a result of combining the accumulation and experience of centuries with modern medicine (Nathan, 2012). However, despite all these developments, infectious diseases are still an important problem of humanity and not only reduce the quality of life but also cause the death of thousands of people around the world every year (Cheng et al., 2003; Ibrahim, 2012).

The reasons why infectious diseases still have such serious consequences are also the reasons for developing new anti-infective agents. Drug resistance, diseases requiring immediate treatment, increased bioavailability, and patient compliance are the reasons for developing new anti-infective agents (Bush, 2004; Nathan, 2012).

Drug resistance

Bacteria, viruses, fungi, and parasites, which cause the infection, develop resistance to anti-microbial drugs over time depending on various factors (National Institute of Allergy and Infectious Diseases, 2011). These factors are examined in four groups:

1. Factors depending on the microbial agents (natural selection, mutation, gene transfer, and social pressure).
2. Inappropriate use (inappropriate use and inadequate diagnostics).
3. The evaluation of resistance hospital strains.
4. Agricultural use.

Anti-microbial resistance (AMR) that develops due to one or more of these factors makes difficult or impossible the treatment of infectious diseases. Today, the most critical reason for deaths due to infectious diseases is AMR (Bush, 2004; Ibrahim, 2012; Ventola, 2015; European Centre for Disease Prevention and Control, 2018; U.S. Department of Health & Human Services Centers for Disease Control and Prevention, 2019). It is essential to isolate these resistant strains and develop anti-infective agents that can act directly on them. On the other hand, clinicians should pay attention to the appropriate use of these new agents to prevent/delay the resistance against them.

Emerging diseases

While the fight against existing known infectious diseases continues, new diseases are also defined by the isolation of new strains that have not been discovered before or due to the mutation of the strains. These diseases may be the reappearance of an old disease such as tuberculosis, whooping cough, chickenpox with resistant strains. There may also be new diseases of viral origin such as AIDS, ebola, and SARS that develop due to new strains (Bush, 2004; Nathan, 2012). The last example of this situation is COVID-19, which has affected the whole world from the end of 2019 and is predicted to be controlled within 2022 with the best estimate. Since the existing anti-infective agents are insufficient to combat these diseases, the disease's risk and rate of transmission are very high and can turn into a pandemic. In such a situation, the immediate isolation of the infectious strain is a critical step in developing new agents that can be used in its treatment. On the other hand, the correct observation of the symptoms of these new diseases and the use of the correct medication for the treatment of them are also very important in terms of symptom management until new agents are developed.

Bioavailability and patient compliance

Bioavailability and patient compliance are the driving forces not only for developing the new anti-infective agents but also for developing the new drugs to be used in the treatment of all diseases, unlike drug resistance and emerging diseases.

In the treatment of infectious diseases, the drugs must be within the therapeutic concentration range in the action area (Bush, 2004). There are two reasons for this situation: The first is to control the disease by keeping the infectious strains under constant pressure and effectively performing the treatment. The second is that strains can develop resistance against drugs used at the wrong therapeutic concentration.

Based of these aforementioned informations, it is understood that new anti-infective agents with high bioavailability, low dosing frequency and side effect profile should be developed and included in treatment protocols.

The importance of developing novel anti-infective drug delivery systems

Most of the drugs on the market are formulated as conventional dosage forms namely solutions, emulsions, suspensions, creams, ointments, gels, and conventional tablets (FDA, 2021). Due to the low bioavailability of some drugs, the dose applied and dosing frequency during the day could be relatively high. When the dose strength was increased, the potential risks of drug related side effects could also increased, that could be resulted in decreasing the patient compliance to the therapy. In order to overcome these limitations novel drug delivery systems targeting drug to the site of the action in the body have been developed.

Drug delivery systems ensure that any drug is delivered to the target area with any suitable carrier such as polymer or surfactant. These systems, which are generally micro or nano-sized, enable transporting lipophilic molecules to hydrophilic tissues or hydrophilic molecules to lipophilic tissues (Hall, 1986). Since they carry the drugs directly to the target tissue, they can achieve therapeutic concentrations in the effect area by administration of much lower doses. Thus, the side effects may reduce. On the other hand, since these systems also provide controlled or sustained drug release, dosing frequency is also very low. All these positive effects also increase patient compliance.

Drug delivery systems have an important role in the treatment of infectious diseases. The drug concentration in the target tissue must remain within the therapeutic range during treatment. While this continuity is ensured with repeated doses with conventional drugs, dosing frequency is lower because drug delivery systems provide controlled drug release (Breimer, 1999; Gao et al., 2011). Because of low dosing frequency, patient compliance increases, and the risk of overdose may be eliminated, which may affect the effectiveness of the treatment. As the anti-infective agents accumulate directly in the target tissue, the applied dose and side effects may decrease thanks to the drug delivery systems. However, perhaps the most important benefit of drug delivery systems in treatment with anti-infective agents is the prevention of resistance due to inappropriate use (Pham et al., 2019).

The other important advantage of drug delivery systems is that they shorten the Research & Development (R&D) process and allow research to be completed with less budget. It takes approximately 15 years to discover a new drug molecule, prove its *in vitro* and *in vivo* efficacy, complete its clinical studies, and complete the licensing process, and be used in treatment (Barrett, 2014). It also requires a budget of close to 1 billion dollars (Adams and Brantner, 2010). In today's conditions where the average life expectancy is prolonged and the total population is constantly increasing, it is not a very practical option to find new treatment agents. For this reason, it is a much more rational approach to remove the old molecules that have been proven to be used in the treatment from the traditional dosage form and to increase their effectiveness by "changing the clothes" (Paolino et al., 2006). This approach is an important method, especially in developing anti-infective agents where there is always a risk of resistance. Given the length of time of discovering the new molecule and brought into use, it is not possible to meet the urgent need for new anti-infective agents. On the other hand, spending such large budgets in this process is not an accurate R&D strategy for these drugs, which are at risk of developing resistance at all times. Also, the mutation of the strains during the phase studies and developing resistance against this new agent waste the entire R&D process (O'Neil, 2011). Based of these informations, it may be more efficient to modify the existing anti-infective agents to improve their pharmacodynamic and pharmacokinetic profiles than developing new agents.

Natural anti-infective agents

Since the fight against infectious diseases has existed throughout human history, many anti-infective agents of natural origin have been discovered and used since ancient times (Cos et al., 2006; Khazir et al., 2013). The existing knowledge has been passed down through generations. Depending on the development of technology, the structures responsible for the anti-infective effect in these natural medicines have been discovered, isolated, or synthetically produced in the laboratory. It also gave an idea for the preparation of new synthetic or semi-synthetic molecules. Some anti-infective agents of natural origin are given in Table 1. Today, these natural resources are still used in the development of new anti-infective agents.

***In vitro* dissolution/drug release assays for anti-infective drug development**

In vitro drug release assay is one of the key performance test to develop new antiinfective agents or their novel delivery systems. *In vitro* dissolution tests (referred to here as “*in vitro* release assays”) are performed to evaluate drug release rate *in vitro* as a function of time. Drug release over time is quantified by using various analytical methods such as spectrophotometric, chromatographic, mass spectrometric, and potentiometric (Wang et al., 2006; Grady et al., 2018). The *in vitro* drug release kinetics can be followed based on different mathematical models including zero order, first order, Hixson and Crowell, Higuchi, Weibull, Korsmeyer-Peppas, Hopfenberg, Baker-Lonsdale and Gompertz models (Ramteke et al., 2014; Dash et al., 2010; Singhvi and Singh, 2011; Vaghela et al., 2011).

At the initial stage of formulation development, *in vitro* dissolution test helps optimizing drug release from formulations. It is useful for initial screening among potential formulations to observe the influence of critical formulation variables and to help in the selection of the candidate formulation. At later stages, it reduces the number of bioavailability/bioequivalence studies by indicating *in vivo* performance of antiinfective drug products (Uddin et al., 2011). *In vitro* release mechanism and kinetics may also affect product manufacturing, stability, quality control, scale-up studies, reproducibility or, in some circumstances, *in vivo* drug release besides formulation development process. Drug release and dissolution are not synonyms but mostly used for each other. The drug dissolution process consists of five steps, including wetting of the particle surface with water, breakdown of solid state bonds in drug particle, solvation, diffusion through the liquid unstirred boundary layer and convection within the bulk fluid. However, drug release is more complex and drug dissolution is only one of drug release steps. The drug release process consists of 4 steps, including drug dissolution in the delivery system upon contact with water after penetration into the drug carrier, drug diffusion out of the delivery system owing to the concentration gradient, changes in the physical shape of the delivery system such as swelling and subsequent drug dissolution in the aqueous medium of the applied tissue (Jug et al., 2018; Azarmi et al., 2007; Uddin et al., 2011).

Dissolution test was first developed to evaluate oral drug release from solid dosage forms such as tablets and capsules. When a drug is administered by oral route in solid dosage forms, it is firstly delivered to the absorption site via gastric emptying and intestinal transit flow and dissolved in the stomach and/or in the small intestine. Then, the dissolved drug is absorbed from the gastrointestinal membrane and passes through the liver and finally reaches the systemic circulation. In particular, dissolution becomes a rate limiting step in the overall release process when poorly soluble drugs are formulated in a conventional dosage form. In this case, the terms of drug dissolution and drug release could be used interchangeably if the drug dissolution process is the rate-limiting stage in the overall release process. Thereby, the long term rate and drug absorption into systemic circulation are regulated by dissolution rate (Jug et al., 2018; Krishna and Yu, 2007). Also, the dissolution test could be used in a variety of dosage forms such as transdermal therapeutic systems, suspensions, suppositories, chewing tablets, powders, inserts, implants, and others besides tablets and capsules.

There are different apparatuses (Apparatus 1–7) used in dissolution tests for drugs and their dosage forms (Second Interim Revision Announcement, 2016). The design and operation of the apparatus, as well as the medium used in dissolution studies, may affect *in vitro* drug release profile and hence drug absorption. The USP defines different apparatuses used in dissolution studies, and has recently been harmonized with the European Pharmacopeia and the Japanese Pharmacopeia. Experimental and simulated conditions are applied during dissolution tests, for example some at room temperature and some at body temperature (32 °C or 37 °C). Apparatus 2 is the most common used apparatus, which is also known as paddle method. It is recommended for dissolution profile testing of immediate-release solid dosage forms. Sinkers in the type of spiral, pronged or basket are used to avoid capsule dosage forms from floating. Apparatus 3 (reciprocating cylinder) is recommended for some extended-release tablets and is advantageous when pH/buffer adjustments are needed during the dissolution testing process, or when hydrodynamics can be directly affected by adjusting the dip rate. Apparatus 1 is a basket type and the second-most-commonly-used dissolution apparatus, enables dissolution tests on floating formulations without sinkers. It is the same apparatus and vessel type as the paddle apparatus, usually with a vessel size of 1 L, but instead of a paddle, the dosage form is kept in a cylindrical basket with mesh openings. Apparatus 4 (flow-through cell) is recommended for extended release and poorly soluble products. Contrary to the other dissolution apparatuses, a piston pump that generates a sinusoidal flow profile is used in the flow-through cell apparatus. As a consequence, the fluid velocity changes over time. Whereas Apparatus 5 (paddle-over-disk) is used for dissolution of topical and transdermal dosage forms, Apparatus 6 (rotating cylinder) is recommended for all methods when needed to assure the quality and performance of topical and transdermal systems. Also, Apparatus 7 (reciprocating holder) is recommended for transdermal patches (Shohin et al., 2016; Todaro et al., 2017; Uddin et al., 2011; Gray and Rosanske, 2020; Culen et al., 2013).

In vitro drug dissolution/release assay has become more important with the developing nano drug delivery systems such as liposomes, micelles, microemulsions, nanoparticles etc. These nanoparticulate systems are mostly used to improve bioavailability, enhance antimicrobial activity by prolonging drug release, microorganism targeted drug delivery, and also reduce possible side effects. In particular, a gradual drug release from nanocarrier systems over time with a mild gradient can reduce bacterial resistance and improve antiinfective drug activity. Considering that any unexpected change in product performance of such systems may result in toxicity or change in the activity. Moreover, novel drug delivery systems exhibit some problems due to the physicochemical properties of the formulations and the properties of the physiological drug release medium. Also, dosage form performance may affect the bioavailability of drugs incorporated in these systems. In this regard, it is important to perform suitable *in vitro* dissolution/release testing methods to assist in antiinfective drug development and ensure pharmaceutical product quality and performance (Jug et al., 2018; Azarmi et al., 2007; Shen and Burgess, 2013; Ebrahimi et al., 2020).

There are various *in vitro* drug release assay methods to meet the requirements nanoparticulate drug delivery systems. Membrane diffusion methods (dialysis methods), sample and separation methods and continuous flow methods are the three general types of these methods. Membrane diffusion methods (such as the dialysis methods) are the most commonly used methods for the *in vitro* dissolution/release testing of the nanoparticulate systems. The nanoparticles are removed from the release medium using dialysis membranes that are permeable to the free drug but not to the nanoparticles. The dialysis sac method, the reverse dialysis sac method and the side-by-side dialysis methods are the types of membrane diffusion methods. Agitation conditions, the ratio between donor and acceptor cell volumes, and most probably, molecular weight cut-off of the dialysis membrane affect drug release in this method. In the sample and separate methods, nanoparticles are included in the release medium and then separated from the medium at different time intervals by using separation methods such as ultrafiltration or ultracentrifugation. Then, the supernatant or filtrate is analyzed in terms of drug amount. Agitation conditions, and most probably, separation methods affect drug release in this method. The continuous flow method uses USP Apparatus 4 and suitable for modified release dosage forms because a small volume of the medium can be constantly circulated through immobilized formulations. Nevertheless, it may be difficult to test dissolution/release profiles in the USP Apparatus 4 system when the nanoparticles are very small (less than 100 nm) so that they can either clog the filter or pass through the filter thus leading incorrect results. These problems were mostly prevented by modifying Apparatus 4 with a dialysis adapter. Also, the methods of membrane diffusion, sample and separation or continuous flow can be combined to assess drug release more properly from nano drug carriers (Shen and Burgess, 2013; D'Souza, 2014; Abdel-Mottaleb and Lamprecht, 2011; Jambhekar and Breen, 2013).

Moreover, there are other dissolution/release test methods such as dynamic dissolution methods and microdialysis methods. Ion- or drug-selective electrodes are used in dynamic dissolution methods to determine release profiles of electroactive drugs from nano drug carriers. For example, electrochemical methods are very advantageous for preventing the interference due to the presence of undissolved dosage form in the release medium. Dynamic dissolution methods are used in combination with mostly USP Apparatus 1 or 2. In microdialysis method, probes are placed into the vessels and continuously perfused with a fresh media through an inner tube. Between the inner tube and the outer dialysis membrane, the medium streams out. Then, the released drug in the medium is analyzed by using analytical methods. Other *in vitro* drug release methods are nonelectrochemical methods such as calorimetry, turbidimetry, light scattering and laser diffraction and the other methods include vertical Franz diffusion cells and *in vitro* lipolysis model (Shen and Burgess, 2013; D'Souza, 2014; Gray et al., 2018; Balzus et al., 2016). Novel, cost-effective, simple and reliable *in vitro* drug release methods are also being developed that is applicable to small volume nanoparticulate formulations. Recently, a 3D printed microfluidic drug release device has been designed with two distinct chip geometries, "basket" and "V" shaped barriers (Amoyav et al., 2021).

For bone infections, Bai et al. (2020) developed roxithromycin incorporated polycaprolacton/polyethylene glycol composite nanofiber scaffolds via melt electrohydrodynamic 3D method. According to *in vitro* release data, the scaffolds exhibited an initial burst drug release and then long-term sustained drug release behavior, which is desirable for the prevention and treatment of bone infections. Drug release reached to higher than 70% at the first 6 h. Also, the scaffolds had antibacterial activity against *Escherichia coli* and *Staphylococcus aureus* via disc diffusion assay. Increasing amounts of polyethylene glycol in the formulations resulted in the enlargement of inhibition zones because polyethylene glycol accelerated drug release. In another study, nanostructured baghdadite-vancomycin scaffolds showed larger inhibition zones against *Staphylococcus aureus* with higher vancomycin concentration in the formulation. Moreover, the scaffolds sustained drug release process promoted the antibacterial effects (Bakhsheshi-Rad et al., 2017). Baig et al. (2016) prepared levofloxacin loaded solid lipid nanoparticles for the treatment of conjunctivitis. *In vitro* drug release assay was performed using Franz diffusion cells with dialysis membrane and exhibited a prolonged drug release following Korsmeyer-Peppas model. Esentürk et al. (2020a) also used Franz diffusion cells to evaluate naftifine hydrochloride release from poly(vinyl alcohol)/sodium alginate nanofiber mats and their crosslinked ones with glutaraldehyde. The burst drug release was decreased with the crosslinking treatment effectively and the release mechanism followed Korsmeyer-Peppas Super Case-II transport. In a study carried out by Durgun et al. (2020), it was shown that the release of posaconazole from the micelle formulations was higher than that of suspension using Franz diffusion cells method. In addition, antimicrobial activity study by agar plate method proved that levofloxacin loaded solid lipid nanoparticles were active against *Staphylococcus aureus* and *Escherichia coli*. Other studies which are evaluating *in vitro* dissolution/release assay for anti-infective drug development are listed in Table 2.

Susceptibility and time-kill assays for anti-infective drug development

Antimicrobial susceptibility assay is one of the important tests used to determine susceptibility of pathogen organisms to anti-infective drugs and assess possible drug resistance. The main aim of susceptibility assay is to predict the results of the treatment with anti-infective agents tested and choose the best anti-infective agent in terms of antimicrobial activity (Benkova et al., 2020).

Antimicrobial activity is usually measured either as a zone diameter (in mm) of the bacterial growth inhibition around an anti-infective drug-containing disk or as a minimum inhibitory concentration (MIC, mg/L) of the drug versus the tested pathogen (Arena et al., 2015). Dose and drug selection in the anti-infective drug development stage is mostly based on an *in vitro* parameter, the MIC, and on the drugs serum concentration as a pharmacokinetic parameter (Miller et al., 2005). MIC is the lowest concentration of the antimicrobial agent that prevents visible growth of the test strain of an organism and expressed in mg/L ($\mu\text{g/mL}$). Susceptibility assay results are usually defined as categories of susceptibility such as susceptible, intermediate or resistant corresponding to the cut-off values provided by scientific committees of EUCAST (European Committee on Antimicrobial

Table 2 The summary of studies in which *in vitro* dissolution/release assay was used to develop different types of delivery systems of antiinfective drug substances.

Antiinfective drug	Delivery system	In vitro dissolution/release method	Results	References
Cephalexin	pH sensitive carboxymethyl cellulose hydrogel beads	Sample and separate method and simulated GIS conditions	Protection from stomach pH and a controlled drug release in the intestinal conditions	Barkhordari and Yadollahi (2016)
Ciprofloxacin	Near-infrared light-triggerable thermo-sensitive hydrogel	Eppendorf tube	Trigger in drug release with NIR irradiation from hydrogel, thereby synergistically enhanced antibacterial activity against <i>Staphylococcus aureus</i>	Gao et al. (2019)
Vancomycin	Injectable hydrogel	Eppendorf tube	Sustained drug release over an extended period of time in a pH-dependent manner Killing methicillin-resistant <i>Staphylococcus aureus</i> bacteria upon contact as well as by releasing antibiotics	Hoque et al. (2018)
Ciprofloxacin	β -Cyclodextrin-Chitosan based sub-microcarrier	Dialysis membrane	Suitable drug-delivery device for local antibiotic therapy Achievement in sufficient amount of drug release before 24 h A promising drug delivery system for the treatment of respiratory extracellular infections	Ho et al. (2018)
Aminoglycosides (netilmicin, isepamicin, capreomycin, ribostamycin, apramycin, amikacin, paromomycin, tobramycin and neomycin)	Hydrogel	Vial	On-demand drug release behaviors High antibacterial activities against <i>Staphylococcus epidermidis</i> , <i>Staphylococcus aureus</i> , and <i>Pseudomonas aeruginosa</i>	Hu et al. (2017)
Nystatin	Self-nanoemulsifying drug delivery system	Dialysis bag	Improvement in the solubilization and release rate of the drug, thus enabling better interaction with the fungi cell membrane and increase in the activity against <i>Candida albicans</i>	Kassem et al. (2016)
Ceftriaxone sodium	Injectable hydrogel	Vial	Localized, sustained drug delivery over 2 weeks for preventing local <i>Staphylococcus aureus</i> infections	Li et al. (2017)
Ciprofloxacin	Nanofibers	Cuvette	Sustained drug release mostly following a non-Fickian diffusion mechanism with a release rate independent of drug concentration	Moydeen et al. (2018)
Curcumin	Nanoliposomes	In artificial gastric and intestinal media	Twofold higher curcumin release in the simulated gastric and intestinal environment	Kumar et al. (2018)
Peppermint and green tea essential oils	Nanoparticles	Dialysis bag	Better antibacterial and antifungal activity than the native curcumin Initial burst release for the first 12 h, then a slow release up to 72 h Better antibacterial activity with nanoparticle formulations against <i>Staphylococcus aureus</i> and <i>Escherichia coli</i> than pure essential oils	Shetta, et al. (2019)

Susceptibility Testing, Europe), CLSI (Clinical and Laboratory Standards Institute, USA) or International Organization for Standardization (ISO) (Dietvorst et al., 2020; Balzus et al., 2017; Khan et al., 2019; Karatuna, 2012). The result category of “susceptible” means that the antiinfective agent is most probably effective in the treatment with the appropriate dosage. The result category of “resistant” means that treatment with the antiinfective agent is presumably to fail (Jorgensen, 2011).

There are various *in vitro* susceptibility assay methods either classical golden standard methods or novel methods based on culture growth or single-cell analysis (Dietvorst et al., 2020; Benkova et al., 2020; Schumacher et al., 2018; Jorgensen and Ferraro, 2009). Diffusion and dilution methods are commonly used golden standard methods which were standardized by organizations of EUCAST and CLSI. Agar disc diffusion method is one of the oldest and the most popular diffusion methods in antimicrobial susceptibility assays. It is simple, reproducible and low cost. Generally, Mueller-Hinton agar plates are inoculated with a standardized inoculum of the test microorganism (corresponding to 0.5 McFarland turbidity standard to have a final microbial concentration of $1-5 \times 10^5$ CFU (colony forming unit) per mL). Paper discs are treated with different concentrations of the tested drugs and then placed onto the inoculated agar surface. The agar plates are incubated under suitable conditions, generally for 16–24 h at 35–37 °C. Then, growth inhibition zones around the paper discs are measured in millimetres. The diameters of the inhibition zones are related to MIC values conversely. In antimicrobial gradient strip method, dilution and diffusion methods are combined. The agar medium is inoculated with the tested microorganism and then thin test strips which are including increasing concentration gradients of the drug are then placed onto the agar surface. The MIC values are determined by looking at the strips from the top of the petri dish and calculating the point where the strips intersect with an elliptical growth inhibition zone. This method is also rapid and easy but more expensive than agar disc diffusion method (Arena et al., 2015; Benkova et al., 2020; Schumacher et al., 2018; Liu et al., 2016). Dilution methods are also reference methods for determining MIC values of antiinfective drugs. Moreover, these methods enable to make a comparison between newly developed antimicrobial agents because the diffusion methods may be unreliable when quantitative results are needed. Broth microdilution (tube dilution) method is an old method and requires larger amounts of reagents but enables quantitative MIC results. In broth microdilution method, small amount of sample is sufficient so that it is more popular and practical as an antimicrobial susceptibility assay. Broth microdilution method is performed by using small 96 well plates that are allowing testing 12 different antimicrobial agents over a range of 8 twofold dilutions on one plate. Twofold diluted antimicrobial agents are put into the trays and the plate is inoculated with a diluted microbial suspension standardized to an optical density of 0.5 McFarland McFarland turbidity standard. Based on the microorganism tested, the plate is incubated under appropriate conditions. The MIC is determined using spectrophotometry at 620 nm. The minimum bactericidal (MBC) and fungicidal (MFC) concentration values are determined by calculating the lowest concentration of antimicrobial agent which reduces the viability of the initial bacterial or fungal inoculum by $\geq 99.9\%$. MBC is determined by subculturing from the microtitration plates on Mueller–Hinton agar plate for 24 h at 37 °C. In the case of determining MFC, Sabouraud agar plates are used and the incubation conditions are 48 h at 35 °C. Another susceptibility test is agar diffusion test, which is not frequently preferred. In this method, different concentrations of an antimicrobial agent is included into a molten agar medium, then, a standardized microbial inoculum was applied to the surface of the agar plate. The agar plates are evaluated by visually comparing various strains in the series, and then, MIC is determined as the lowest antimicrobial agent concentration that inhibits growth (Benkova et al., 2020; Balzus et al., 2017).

Due to the disadvantages of the golden standard methods, novel *in vitro* susceptibility tests have been developed. Fluorescence based test kits are used for assessing cell viability by staining either dead or live cells selectively with a fluorescent marker. In mass sensitive technology, cantilevers are used and microbial deposition on the beam produces resonant frequency changes. The differences are detected using various instruments. In another method, forward laser light scattering is used to detect microorganisms with the sizes from 100 to 10.000 nm by a laser in the range of 400–700 nm. Also, there are live-cell imaging and real-time microscopy systems on the market, which are combining with a microfluidic system and a fully automated fluorescence *in-situ* hybridization system, respectively. Polymerase chain reaction (PCR) and matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) instruments have also been combined to susceptibility assay recently. Moreover, novel susceptibility tests are still being developed such as colorimetric, electrical and isothermal microcalorimetric methods, and others utilizing flow cytometry, Raman spectroscopy, laser tweezers, microfluidic technologies and motion tracking (Dietvorst et al., 2020; Benkova et al., 2020; Idelevich and Becker, 2019; Schumacher et al., 2018; van Belkum et al., 2020; Pulido et al., 2013; Spencer et al., 2020).

Potency of antiinfective drugs and their interaction with pathogens are currently predicted mostly using susceptibility assay by measuring MIC values. However, they do not provide any information about the antimicrobial activity over time and may have different modes of action and lead to different treatment outcomes. The rate of bacterial killing and time before regrowth of surviving microorganism may affect the design of an optimal dosing interval. Thus, there is need to better understand the *in vitro* pharmacodynamic and pharmacokinetic properties of antiinfective drugs to optimize dosing regimens for drug candidates early in the early antiinfective drug development process and prevent treatment failures. Also, some of the microorganisms represent different growth phases such as that drug-induced killing may exhibit a rapid initial period, accompanied by a decrease in killing rate. Time-kill assay is frequently used in development of new antimicrobial agents and provides monitoring microbial growth and death over a wide range of antimicrobial concentrations over time. These data can be analyzed using mathematical models and are usually the first step in the pharmacodynamic and pharmacokinetic modeling. According to the CLSI guidelines for the standardized time kill assay, bactericidal activity is defined as a reduction of 99.9% of the value of cfu/mL ($\geq 3\log_{10}$), bacteriostatic activity is defined as maintenance or reduction of 99.9% of the value of cfu/mL ($<3\log_{10}$) and synergism is defined as a $2\log_{10}$ cfu/mL decrease from the most active agent alone in the colony count after 24 h (NCCLS, 1999). The time kill assays are mostly used in preclinical studies due to being an easy assay and cheap. However, the problem in time-kill assay is microbial regrowth after initial

reduction in the starting inoculum, which is caused by the selective killing of the susceptible sub-population along with selective amplification of the resistant sub-population (Tam et al., 2005; Foerster et al., 2016; Vaddady et al., 2010; Onufrak et al., 2016).

The most popular approach of antibiotic dosing is to adjust the doses to maintain antimicrobial plasma concentrations above the MIC for a given pathogen over the course of the dosing interval. Antiinfective drugs are classified in two groups based on the pattern of antimicrobial activity. The first group is concentration-dependent killing over a wide range of concentrations, which is resulting in a higher rate and degree of killing with higher concentrations. The pharmacodynamic parameter for concentration-dependent drugs can be simplified as a peak/MIC ratio. For example, intracellularly acting drugs such as aminoglycosides, azalides (azithromycin), ketolides, vancomycin, rifamycin and quinolones follow this pattern. The second group is time-dependent killing, in which drug exposure time lets the drug to bind to the microorganism. The pharmacodynamic parameter for time-dependent drugs can be simplified to the time that serum concentrations remain above the MIC throughout the dosing interval to have cidal effect ($t > \text{MIC}$). For example, antibiotics that targets cell wall such as beta-lactams (penicillins, cephalosporins), clindamycin, macrolides (erythromycin, clarithromycin and except for azalides), oxazolidinones (linezolid), tetracyclines and clindamycin follow this pattern. Indeed, there are numerous antimicrobial drugs which do not follow these classical pattern of classes, but remain in between (Vaddady et al., 2010; Mouton, 2011; Gao et al., 2011).

The results of the time-kill assay are obtained as time-kill curves which can be analyzed using appropriate pharmacokinetic-pharmacodynamic models. These *in vitro* models enable direct comparison of the results of various concentration profiles and more accurate evaluation of the pharmacokinetic-pharmacodynamic relationship than *in vitro* susceptibility assays. There are two classes of *in vitro* models. The first group of constant drug concentrations evaluates constant concentration of drug against microorganism as a function of time. In the second group of variable drug concentrations, drug concentrations fluctuate by dilution or diffusion (Miller et al., 2005).

A new anti-infective agent, Titroleane™, which is obtained from tea tree oil was investigated in terms of its antimicrobial activity using the broth microdilution method. It presented good activity against skin and soft tissue infection pathogens such as methicillin resistant *Staphylococcus aureus*, intra-abdominal infections and oral pathogens, and also fish farming pathogens. The MIC values varied from 0.08% to 2.5%, except for *Campylobacter jejuni*, and *Aspergillus niger* for Titroleane™ (Johansen et al., 2020). Also, novel formulations of antiinfective agents can be assessed in terms of susceptibility. Durgun et al. (2021) prepared posaconazole micelle formulations and confirmed their antifungal activity against *Candida albicans* strains using disc diffusion susceptibility method. Qurt et al. (2018) developed microemulsion formulations as a nano-sized colloidal carrier for dermal delivery of voriconazole or sertaconazole. The formulations found effective against *Candida albicans* species by determining MIC values by the microdilution method.

In order to obtain better antibacterial effect in acne treatment, rifampicin was loaded into niosomal carriers, which improve skin retention of drugs. The prepared formulations showed sustained drug release at controlled rate. Time kill study against *Propionibacterium acnes* and *Staphylococcus epidermidis* also showed that up to 96% of bacteria were killed within 4 h (Begum et al., 2015). Also, spectinamides with the names of 1599 and 1445 as early major candidate antibiotics under development for the treatment of tuberculosis. In order to help in candidate selection and dosing optimisation, time kill curve assays were performed. The results showed that 1599 exhibited concentration-dependent killing whereas 1445 showed time-dependent killing against *Mycobacterium bovis* BCG (Vaddady et al., 2019). In another study, an highly lipophilic antifungal drug, sertaconazole nitrate, was incorporated into polyurethane/polyvinylpyrrolidone/silk fibroin nanofibers and the MICs of the formulations were determined by broth microdilution method. Then, time-kill analysis data showed that all of the drug incorporated formulations showed fungistatic activity against *Candida albicans* during 6 h with average 0.30 log₁₀ cfu/mL decrease. Indeed, this activity was not concentration-dependent for all formulations (Esenturk et al., 2020).

Colistin is an antibiotic drug used to treat the infections by Gram negative bacilli. However, colistin-resistant *Acinetobacter baumannii* and *Klebsiella pneumoniae* strains have occurred in the last years. Ayerbe-Algaba et al. (2018) studied *in vitro* activity of niclosamide in combination with colistin against colistin-susceptible and colistin-resistant *Acinetobacter baumannii* and *Klebsiella pneumoniae* strains using broth microdilution assay and time-kill assay. It was shown that there was an antagonism by niclosamide on the antibacterial activity of colistin against the strains in the first 4 h. However, the combination enhanced the activity of colistin against colistin-susceptible and especially colistin-resistant *Acinetobacter baumannii* and *Klebsiella pneumoniae* strains at 24 h. Babii et al. (2018) investigated antibacterial activity of a novel synthetic sulfur containing tricyclic flavonoid, ClCl-flav, against *Staphylococcus aureus*, *Escherichia coli* and *Klebsiella pneumoniae* using colorimetric broth microdilution method and time-kill assay. The compound was more susceptible to Gram positive bacteria (MIC = 0.24 µg/mL) than Gram negative ones (MIC = 3.9 µg/mL) and had 32 to 72-fold more activity than other synthetic flavonoids. ClCl-flav exhibited bactericidal activity at concentrations ranging from 0.48 to 15.62 µg/mL. At the concentration of 2 × MIC, *Escherichia coli* and *Klebsiella pneumoniae* cells were killed within 1 h. In another study, antibacterial activity of omadacycline, which is a novel tetracycline class antibiotic drug, was assessed against *Mycobacterium abscessus* that causes severe lung infections. Omadacycline exhibited bacteriostatic activity at 4 mg/L and also bacteriocid activity at the concentration of 16 mg/L. Time-kill curves presented strong concentration-dependent antimicrobial activity for omadacycline (Bax et al., 2019).

Menezes et al. (2020) investigated the effect of daptomycin against vancomycin-resistant *Enterococcus faecium*. Time-kill curve data were used in computer modeling and Monte Carlo simulations to determine the logarithmic reduction in the number of colony-forming units (CFU)/mL with different doses of daptomycin. There was a reduction as >2log CFU/mL over 18 days of daptomycin treatment with doses of 6–10 mg/kg/day in strains with a MIC value of 2 µg/mL. Other studies which are evaluating time-kill curves after susceptibility assay for antiinfective drug development are listed in Table 3.

Table 3 The summary of studies in which time-kill curves after susceptibility assay was used to develop an anti-infective drug.

(2017)
<i>Glycyrrhiza glabra</i> extract and glycyrrhizic acid	<i>Pseudomonas aeruginosa</i>	Broth dilution	Rapid and significant decrease in growth with the extract t 12 h Decrease in growth up to $\sim 1 \log_{10}$ with glycyrrhizic acid and no growth at 24 h	Chakotiya et al. (2016)
Dalbavancin	<i>Staphylococcus aureus</i> and <i>Staphylococcus epidermidis</i> biofilms	Broth microdilution	Time-dependent and concentration-dependent antibiofilm activity A therapeutic option for the treatment of biofilm-associated orthopedic infections, osteomyelitis and biomedical implant infections	Di Pilato et al. (2020)
Fluoxetine and fluconazole combination	<i>Candida albicans</i>	Broth diffusion	Synergistic activity against <i>Candida albicans</i> with the combination Synergistic activity for the biofilms formed over 4, 8, and 12 h Confirmed synergism dynamically by the time-kill curves	Gu et al. (2016)
Sitafloxacin	<i>Neisseria gonorrhoeae</i>	Agar dilution and Etest	Rapidly killing the highly sitafloxacin susceptible <i>Neisseria gonorrhoeae</i> strains at concentrations higher than MIC	Ito et al. (2018)
Voriconazole	<i>Candida albicans</i>	Microdilution broth	Decrease in average $2.00 \log_{10} \text{ cfu/mL}$ at $1/2 \times \text{MIC}$, $1 \times \text{MIC}$, and $2 \times \text{MIC}$ concentrations and $3.30 \log_{10} \text{ cfu/mL}$ at $4 \times \text{MIC}$ concentration after 4 h, exhibiting dose dependent fungicidal activity	Esentürk et al. (2020b)
β -Caryophyllene and <i>Murraya paniculata</i> essential oil	<i>Staphylococcus aureus</i> and <i>Fusarium solani</i>	Microdilution broth	Rapid bacterial killing (4 h for <i>Staphylococcus aureus</i>) and fungicidal effect (2–4 h for <i>Fusarium solani</i>) by essential oil or β -caryophyllene	Selestino Neta et al. (2017)
Ceftazidime-avibactam	Carbapenemase-producing <i>Klebsiella pneumoniae</i>	Microdilution broth	Significant bactericidal activity against the resistant bacteria strains by ceftazidime-avibactam at the concentrations of $2 \times \text{MIC}$, $4 \times \text{MIC}$ and $8 \times \text{MIC}$	Zhang et al. (2018)
Colistin	<i>Pseudomonas aeruginosa</i>	Disk diffusion	Comparable antibacterial activity with the colistin released from hydrogels as the colistin solution A slow killing profile with the colistin-loaded hydrogels	Zhu et al. (2017)
SCY-078	<i>Candida albicans</i> , <i>Candida parapsilosis</i> and <i>Candida tropicalis</i>	Microdilution broth	Fungicidal activity against <i>Candida</i> spp. with SCY-078	Scoreaux et al. (2017)

Conclusions

The fight against infectious diseases is a worldwide health phenomenon that has been up-to-date since ancient times. Anti-infective agents obtained from natural sources in the early ages of humanity have been used over the years and have enabled the preparation of new synthetic or semi-synthetic anti-infective agents. Despite all these technological developments, new anti-infective agents are needed due to factors such as the development of resistance, emerging diseases, and low bioavailability. However, the R&D process of a new drug molecule is both very long and very expensive. For this reason, it is a very rational approach to develop novel drug delivery systems by modifying existing anti-infective agents, which can help to improve their pharmacokinetic and pharmacodynamic profiles. On the other hand, with the isolation of new strains and the discovery of new diseases, the search for new anti-infective agents should continue reasonably.

Drug release and time-kill assays profiles play a key role either in the discovery of new anti-infective agents or the development of drug delivery systems of known drug molecules. Basic information about the effectiveness of an agent on an infectious strain is obtained by *in vitro* time-kill assays. On the other hand, with the release studies, it is determined whether that drug or dosage form can be at the therapeutic concentration in the target area, in the desired period. Both drug release and time-kill tests, which are carried out with simple *in vitro* techniques, take the basic steps for the development of new anti-infective drugs and, provide preliminary information about the performance of drug products, clinical effect or place in the treatment.

Introduction

The threat of [antibiotic resistance](#) directly targeting human life has been growing for a long time and [appears to be getting worse](#). Antimicrobial resistance occurs when microbic germs develop the ability to defeat the drugs designed to kill them. While antibiotic resistance is a term limited to bacteria, antimicrobial resistance means the resistance showed by microorganisms, which include bacteria, viruses and fungi. Currently, antibiotic resistance is one of the top most serious and complex public health problems throughout much of the world. The main reason of this negative situation is the antibiotic misuse, as well as the potential for the spread of resistant microbes and the emergence of resistance genes, correlated with a reduced number of new antimicrobials that can be effective against these super pathogens (superbugs). Urgent measures are required to be taken before it reaches a critical point, when many people in populations cannot be treated for life-threatening infections owing to lack of effective antibiotics. The World Health Organization (WHO) Global Action Plan on Antimicrobial Resistance announces that discovery of new antimicrobial molecules and increasing awareness of antimicrobial resistance, fulfilling proper surveillance to figure out the prevalence and arrangements of resistance throughout the world are equally important efforts and parts of the solution for antimicrobial resistance.

It is necessary to know the historical aspects in order to understand the fundamentals and all aspects of evolution of antimicrobial resistance. However, the origin of antimicrobial resistance is still a controversial topic. It would be easy to postulate that antimicrobial resistance is a recent problem throughout much of the world; however, antimicrobial resistance has existed long before antimicrobials were discovered, synthesized, or marketed. A previous study has shown that bacterial strains over 2000 years old isolated from glacial waters demonstrate resistance to ampicillin ([Dancer et al., 1997](#)) and some strains from permafrost over 30,000 years old carry resistance to vancomycin ([D'Costa et al., 2011](#)). From the traditional point of view, antibiotic resistance is frequently considered to be a trait acquired by previously susceptible bacteria, the fundamentals of which can be based on the horizontal acquiring of new genes ([Davies 1997](#)). Recent developments in microbial ecology have led the term of the antibiotic resistance to explain how intrinsic resistance may occur and spread within bacteria which can be defined as an environmental reservoir of all antibiotic resistance genes and also their precursors in both pathogenic and non-pathogenic bacteria ([D'Costa et al. 2006](#); [Gaze et al. 2013](#)).

Penicillin was discovered in 1928 and administered clinically in the 1940s. Since the [discovery of penicillin](#) compound, antibiotics have considerably changed modern medicine. The elucidation of penicillin has been an important cornerstone in the knockout treatment of bacterial infections. Sulfonamides, an important family of antibiotics, were subsequently introduced clinically in the 1930s. Many natural or synthetic antimicrobial molecules regarding different infectious diseases were discovered during the 20th century (e.g., 1940s through 1960s), which was a Golden Age for antibiotics. These molecules struggled with bacterial infections by killing or inhibiting the growth of bacteria. Initially, penicillin and other antibiotics were purified from microorganisms e.g., fungi and bacteria found in nature. Synthetic antibiotics began to be produced in the following years. Therefore, the origin of antibiotics is natural substances synthesized to antagonize or inhibit the growth of other microbes, presumably owing to an evolutionary progress that conserves environmental niches of the producing microbes. Pretty soon the

scientists realized many bacteria were developing resistance to antibiotics by evolving and mutating to the points where antibiotics are targeted. Currently, there are over 100 antimicrobial substances available and it is now evident that antimicrobial resistance is inevitable (Fong 2019; Davey and Wilcox 2007).

How antibiotic resistance develops

Due to the increasing threat that antibiotic resistance poses, it is crucial to first understand the genetic fundamentals of bacterial resistance in order to tackle the problem. Antibiotic resistance is classified as the intrinsic (native) or acquired. Intrinsic resistance is a naturally occurring phenomenon that predates antibiotic chemotherapy which occurs regardless of antibiotic exposure. It is found within the genome of a group of bacterial organisms. Typically, the intrinsic resistance is chromosomal-based and can be estimated considering the taxonomic levels of the bacterial species (Cox and Wright 2013). Genes encoding efflux pumps can either be found on both plasmids (e.g., transmissible elements) or on the chromosome. The classic example of intrinsic antibiotic resistance is the multidrug resistant (MDR) phenotype displayed by Gram-negative bacteria, which are insensitive to most clinically effective Gram-positive antibiotics. The molecular basis of this resistance is the existence of the Gram-negative outer membrane, which is impermeable to many substances, and expression of various MDR efflux pumps that dramatically decrease the intracellular amount of the given drug (Nikaido, 1994).

More recent studies have revealed that intrinsic antibiotic resistance has not appeared owing to the selective pressure of antibiotic use. This situation is not considered as simple as permeability barriers and efflux, but a complicated network of genetic loci that contribute to this phenotype. A recent discovery that soil-dwelling bacteria, most of which are non-pathogenic, are rich sources of biotechnologically resistant determinants, the intrinsic resistance of bacteria has become an exciting new therapeutic target for the design of combinations of drugs (codrugs) that potentiate existing antibiotics. Deletion of elements that consist of the intrinsic resistance renders bacteria hyper-susceptible to antibiotics (Liu et al. 2010). This finding suggests that if it were possible to inhibit these targets, it could be potentiated the activity of various present antibacterial agents, supplied with an expanded armory against previously resistant bacteria (Fig. 1).

Intrinsic antibiotic resistance

Conventional mechanisms of intrinsic or natural antibiotic resistance is a characteristic of all strains from species, which is always transmitted to offspring (vertical transmission). It is the result of the mechanisms: (i) an absence of outer membrane permeability, which inhibits the entry or accumulating of antibiotics inside the bacterial cell, (ii) the existence of efflux pumps, which eject antibiotics and other antimicrobial substances from inside to outside media, (iii) modifying enzyme systems e.g., antibiotic modifying enzymes, target-modifying enzymes, and (iv) an absence of molecular target sites required by the antibiotic for binding, even if the antibiotic enters the cell (Cox and Wright 2013; Michăescu et al., 2007) (Table 1).

Fig. 1 Schematic representation of bacterial vertical and horizontal resistant ways.

Tetracyclines	Fluoroquinolones	Rifamycins	Vancomycin
Macrolides		Macrolides	Macrolides
Fluoroquinolones			Fluoroquinolones
			β -Lactams

Outer-membrane permeability

The one of the most important structural differences between Gram-positive and Gram-negative bacteria are primarily related to their cell wall composition. Gram-positive bacteria have cell walls composed mostly of a substance unique to bacteria known as *peptidoglycan*, or murein. Gram-negative bacteria have cell walls with only a thin layer of peptidoglycan and an outer membrane with a lipopolysaccharide component not found in Gram-positive bacteria. Scientists have shown that the peptidoglycan of Gram-positive bacteria possess a great permeability threshold and this is attainable to molecules of up to 30–57 kDa (Scherrer and Gerhardt 1971), its relatively thick peptidoglycan layer lets small molecules to easily penetrate, which is the molecular basis underlying why Gram-positive bacteria are more intrinsically susceptible to various antibiotics (Randall et al., 2013).

However, Gram-negative bacteria are intrinsically insusceptible to many of these antibiotics due to the existence of a much finer molecular sieve and asymmetrical lipid bilayer called outer membrane which covers the relatively thin peptidoglycan layer (Vaara, 1992). The outer membrane is usually thought of as part of the outer leaflet of the dynamic membrane structure and contains structures that help bacteria adhere to targeted cells. Unlike the most of biological membranes, Gram-negative bacteria possess an outstanding lipid composition called lipid A molecules which covalently bonded to polysaccharide units. The periplasmic space includes the periplasm of a concentrated gel-like matrix. The periplasm space can also act as reservoir for virulence factors and a dynamic flux of macromolecules representing the cell's metabolic status and its response to environmental factors. On the other hand, the fatty acid chains within the lipopolysaccharides are generally saturated which allows for tight packing of the hydrocarbon chains which contribute to reducing membrane fluidity (Obst et al., 1997). The outer membrane of Gram-negative bacteria is impermeable to specific classes of antibiotics such as glycopeptides, macrolides, lincosamides, streptogramins.

The role the outer membrane acts in reducing the intrinsic susceptibility of Gram-negative bacteria to many antibiotics is very clear. Outer membrane-based intrinsic resistance is particularly apparent in the opportunistic pathogen *Pseudomonas aeruginosa*.

Efflux pumps

Bacterial cells have highly conserved DNA sequences in their genome that are transcribed and translated to efflux pumps which are capable of moving a variety of different toxic substances out of extracellular area e.g., antimicrobials, heavy metals, organic pollutants, naturally occurring antimicrobials, and quorum sensing signals through active efflux pumps. Over 300 gene products are recommended to transport known substances effectively, out of which ~20–30 transport antibiotics and other drugs. This active efflux pumps are in fact major cellular products and responsible for various types of resistance to bacterial pathogens because bacteria could have adapted efflux pumps to canalize toxins out of the cytoplasm and into extracellular media (Blanco et al. 2016).

With the prokaryotic kingdom, there are six major families of efflux proteins that span the bacterial membrane: the adenosine triphosphate (ATP) binding cassette (ABC) superfamily, the major facilitator superfamily (MFS), the proteobacterial antimicrobial compound efflux (PACE) family (Hassan et al. 2013), the multidrug and toxic-compound extrusion (MATE) family (Kuroda and Tsuchiya, 2009), the small multidrug resistance (SMR), and the resistance-nodulation-division (RND) (Tseng et al. 1999). Whereas RND and PACE efflux pumps are unique to Gram-negative bacteria, MATE, ABC, SMR, and MFS are found in both Gram-positive and Gram-negative bacteria (Nikaido 2011; Hassan et al. 2018).

Efflux pump mediated antibiotic resistance was firstly discovered as a mechanism of resistance to tetracycline (McMurtry et al. 1980). Recently, it is well-documented that efflux pumps form the most type of resistance component, and exist in all organisms from prokaryotes to superior eukaryotes, among those that have been explained. Active efflux pumps can either be molecule specific, and only export one substrate, or they can also be more broad-range, and export structurally different classes of substrates (Piddock, 2006). It has been suggested that efflux pump mediated antibiotic resistance might be a random by product of the broad-spectrum molecule specificity displayed by such pumps; characteristically efflux pumps transport more than one substrate and they frequently exclude toxic substances that have been synthesized by the host (Piddock, 2006).

Deletion of elements of a putative efflux system (MexAB-OprM) in *Pseudomonas aeruginosa* transformed the strain hyper-susceptible to distinct antibiotics to which it was previously resistant (Poole et al., 1993), suggesting that certain classes of antibiotics cannot be used to treat infections caused by bacteria relative intrinsic resistant. It is well-documented that antibiotic-inactivating enzymes, such as β -lactamases, can be intrinsically expressed in certain enterobacteria like *Enterobacter cloacae*, causing resistance to aminopenicillins (De Almeida et al., 2017).

Acquired resistance

Resistance to antimicrobials can also be categorized as acquired which occurs when one encounters bacteria that were initially susceptible but then become resistant to antibiotics. While many factors are effective in the development of acquired antibiotic resistance, the main drivers are antibiotic overuse or misuse. Acquired antimicrobial resistance occurs either through gene mutations or through the obtaining of foreign genetic material that encodes resistance genes.

Because bacteria can reproduce rapidly, this can cause evolutionary changes through random gene mutations which could be seen in relatively short periods. Overexposure to antimicrobials forms an evolutionary selection pressure on bacteria and gives a selective survival advantage that has achieved the resistance mutations (Oz et al. 2014). One of the mechanisms of acquired antibiotic resistance is the modification of the specific targets for antibiotics. When antibiotics are accumulated into the bacterial cell at a sufficient level, they bind specific targets which are generally constitutional proteins. Numerous strains become resistant to certain antibiotics through a mutation process, which led to the synthesis of a modified target protein, which had a low affinity for the antibiotic. A recent paper has shown that substituting even a single amino acid into a target protein structure can lead to changes in its ability to bind antibiotics (Kotra et al., 2000).

The modification of the multimodular penicillin binding proteins which are involved in cell wall synthesis is the one of the best examples. Modification of penicillin binding proteins can lead to loss of affinity for β -lactam antibiotics. The reduced binding affinity is usually associated with the acquisition of a new form of penicillin binding proteins.

For example, the acquisition of a gene encoding a different enzyme, called *PBP2a*, which has much lower affinity for antibiotics than the wild type form results in resistance to antibiotics in staphylococci (Michăescu et al., 2007).

Acquired antimicrobial resistance may be caused by serial mutations or horizontal gene transfer between strains of the same or different species. Normally, genetic materials are passed down from parent to progeny called vertical gene transfer. Additionally, bacteria and some lower eukaryotes are unique in that they can transfer genetic material from one cell to another, a process known as horizontal gene transfer. There are three ways for bacteria to transfer their genetic material horizontally: conjugation, transduction, and transformation.

Conjugation is the transfer of genes directly from one cell to another through cell-cell contact in which DNA molecule is transferred between bacteria through a tube between the cells. In transduction, genetic material is accidentally moved from one to another through bacteriophage mobility. Transformation is direct uptake of piece of DNA molecule from the environment, usually from a lysed bacterium (Fig. 2).

Fig. 2 Schematic demonstration of bacterial gene transfer ways.

Antibiotic resistance genes are generally integrated on plasmids, but they also can reside on genomic islands, insertion sequences, miniature inverted repeat transposable elements, mobile genetic elements (transposons, integrons). Additionally, bacteria can also transfer plasmids to one another through a process termed conjugation. Resistant genes can be exchanged between plasmids and chromosomes, between bacteria, and even bacterial species (Levy 2002).

Plasmids are relatively small (4–400 kbp), extrachromosomal self-replicating DNA molecule which is physically separated from chromosomal DNA. Naturally occurring plasmids are most commonly found as double-stranded (dsDNA) and covalently closed circular DNA (ccDNA) in bacteria which can replicate independently within a cell. In nature, plasmids often carry resistance to (i) one or more groups of antibiotics, (ii) to heavy metal cations (Hg^{2+} , Ni, etc.) and (iii) to anions (bromine, tellurite, etc.) (iv) intercalating compounds like acridine, virulence genes enabling the host cell to survive in an environment that would otherwise be lethal or restrictive for growth (Grumezescu et al. 2016). Gene names and functions on conjugative and mobilizable plasmid vary from plasmid to plasmid.

Certain plasmids might be conjugative, also known as male factors, conjugons, transferons, fertility factors, playing an important role in the dissemination of antibiotic resistance genes (Sandegren et al., 2012). The transfer of plasmid-associated antibiotic resistance is generally versatile and might be both vertically and horizontally among pathogens; however, it is also possible between pathogenic and commensal bacteria. Plasmids can be disseminated rapidly through bacterial communities. For example; the CTX-M extended-spectrum β -lactamases (ESBLs), frequently linked to resistance in *Escherichia coli*, evolved as a plasmid encoded enzyme from environmental *Kuvera* genus (Davies and Davies 2010).

Transposons (jumping genes) are mobile genetic elements that can change its position within a genome, sometimes creating or reversing mutations and altering the cell's genetic identity and genome size. Transposons make up a large fraction of the genome which are responsible for much of the mass of DNA in a eukaryotic cell. They are important vehicles of resistance to antibiotics particularly streptococci (Gram-positive bacteria), but also occur Enterobacteriaceae (Bourque et al. 2018).

Insertion sequences are the simplest transposable elements described in bacteria which consist of approximately 1000 bp DNA sequence. They are cryptic mobile DNA elements and only code for proteins implicated in the transposition activity. Insertion sequences modulates gene expression, efflux mechanisms, resulting in contribute to antibiotic resistance. For example; IS1 and IS10 insertion causes the tripartite overexpression of AcrAB/TolC efflux pump *Salmonella enterica*. Insertion sequences could move either conservatively or replicatively (Siguier et al., 2014).

Integrons are mobile genetic platforms with specific structure that allow bacteria to adapt and evolve rapidly through the stockpiling, excision and expression of new genes. They are embedded in a specific genetic structure termed integron cassette that usually carries one promoterless open reading frame (ORF) together with a recombination site (*attC*). Integron cassettes are incorporated to the *attI* site of the integron platform by site-specific recombination reactions mediated through the integrase enzyme (Escudero et al., 2015). The mobility of resistance genes in other plasmid or in chromosome triggers the possibility of the linked transfer of gene clusters, which causes the simultaneous acquisition of several genes for resistance to several classes of antibiotics, causing the occurrence of MDR phenotypes. Integrons carry a wide variety of genes encoding β -lactamases (Andreotti et al. 2007).

Bacterial biofilms are generally pathogenic in nature and can cause nosocomial infections. Infections with bacterial or fungal biofilms have appeared as a major public health concern since biofilm-growing cells are considerably resistant to both antibiotics and host immune defenses. A recent paper has revealed that biofilm-associated infections demonstrate a significant complexity for the fact of resistance and treatment of chronic infections, which are participated in approximately 65–80% of all infections in developed countries (Lewis 2007).

Multiple drug resistance (MDR) or multidrug resistance

Bacteria can possess not only intrinsic but also acquired resistance as well as more than one mode of action of resistance. This can cause multidrug resistant (MDR), the extensively drug resistant (XDR), and pan drug resistant (PDR) phenotypes. PDR means resistant to all antimicrobial agents. A group of international scientists came together through a joint initiative by the European Centre for Disease Prevention and Control (ECDC) and the Centers for Disease Control and Prevention (CDC), to form a standardized terminology in order to explain acquired resistance phenotypes, known as ESCAPE i.e., *Enterococcus* spp., *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter* spp., *Pseudomonas aeruginosa*, *Enterobacter* sp., and all bacteria responsible for the majority of hospital-acquired infections and prone to multidrug resistance in Stockholm in January 2008 (Magiorakos et al. 2012).

Explaining different stages of MDR in pathogens, the distinct terms extensively drug-resistant and pandrug-resistant were introduced. Extensively drug-resistant states the non-susceptibility of one bacteria species to all antimicrobial agents except in two or less antimicrobial categories. Within XDR, pandrug-resistant (PDR) means the non-susceptibility of bacteria to all antimicrobial agents in all antimicrobial categories. The explanations were published in the Clinical Microbiology and Infection in 2011 within openly accessible (Magiorakos et al. 2012).

Mechanisms of antimicrobial resistance

It is significantly important to understand the specific molecular mechanisms in order to put into effect the new approaches and therapeutic strategies. Broadly, the resistance mechanisms can be outlined as follows:

- Reduced drug uptake through either reduced outer membrane permeability or increased active efflux of the antimicrobials across the cell envelop.
- Antimicrobial inactivation and/or modification by the way production of specific enzymes that both damage or alter the drug, rendering it inactive.
- Target shifts or binding site shifts e.g., changing of penicillin binding proteins.
- Biochemical driving force through metabolic pathways, such as enterococci uptake folic acid from outside and use to neutralize the effects of trimethoprim sulfamethoxazole.

Naturally occurring antimicrobial compounds and their mode of action

Awareness of antibiotic resistance shifted the research focus toward naturally occurring compounds with antibiotic actions. Since ancient times, natural sources such as plants, fungi, bee products have been experimentally used to cure numerous infectious diseases. Doubtlessly, naturally occurring products are the source of most of antibiotic scaffolds in current clinically used drugs. Some plant-based essential oil components are well known for their antimicrobial properties such as flavonoids and they have been shown to act both at the level of the bacterial cell wall and on protoplasmic components (Arslan and Celik 2008; Celik et al., 2008). The proposed antibacterial mode of actions of the essential oils contain the breakdown of cell walls, cell membrane damage with changing permeability, leading to loss of cell substance; inhibition of protein and nucleic acid synthesis, coagulation of protoplasm, the degradation of membrane proteins, consequently reducing the proton move force. For example; phenolic acids were discovered to trigger remarkable changes in the cell wall's hydrophobicity, causing the formation of pores in the plasma membranes that arrest nucleic acid synthesis and energetic metabolism in both Gram-positive and Gram-negative bacteria (Del Rio et al. 2013; Mandal et al., 2010).

Brief descriptions of the most prominent, clinically approved and their antibacterial modes of actions are summarized below.

β -Lactams

All β -lactam antibiotics consist of a 4-membered β -lactam ring system as carbon-skeletal backbone and bind to penicillin-binding proteins. Clinically, five classes of β -lactams including penams, cepheems, carbapenems, clavams, monobactams are important (Fig. 3A). The electrophilic β -lactam antibiotics mimic the D-Ala-D-Ala termini of the pentapeptide part of peptidoglycan layer (Fig. 3B). Penams, cepheems, and carbapenems covalently bind to penicillin binding proteins, preventing the enzyme transpeptidase (Tipper and Strominger, 1965).

Penicillins are naturally occurring compounds belonging to a special class of compounds, the β -lactam antibiotics, of great clinically, pharmacologically, and economically importance. β -lactam antibiotics are typically used to treat a broad array of Gram-positive and Gram-negative bacteria. Natural penicillins are derived from the *Penicillium* fungi/mold and produced from the fermentation of the fungus *Penicillium chrysogenum*. The cephalosporins are a class of cephem-based β -lactam antibiotics originally derived from the fungus *Cephalosporium* (Wilke et al., 2005; Sharma et al. 2007).

β -Lactam resistance

β -lactamases are enzymes (E.C.3.5.2.6) synthesized by bacteria which hydrolyze the β -lactam ring structures of β -lactam antibiotics, and terminate the effects of them. Gram-negative bacteria possess β -lactamase-mediated antibiotic multi-resistance but have also been described in *Staphylococcus aureus* (Wilke, Lowering, Strynadka 2005). β -Lactamases inhibitors such as clavulanic acid, sulbactam and tazobactam have been introduced to overcome the β -lactamases activity.

Extended-spectrum beta-lactamase (ESBL)

These enzymes commonly express β -lactamases such as TEM-3, TEM-4, and SHV-1 which confer multi-resistance to a broader expanded-spectrum cephalosporins. The ESBLs confer resistance to penicillins, third generation cephalosporins such as cefotaxime, ceftriaxone, and ceftazidime, and monobactam aztreonam (Emery and Weymouth, 1997). However, a recent research has demonstrated that certain β -lactamase and ESBLs are genetically linked genes (Bradford 2001).

Aminoglycosides

Streptomycin was firstly discovered from a strain of *Streptomyces griseus* with aminoglycoside structure by Waksman and colleagues (Waksman et al., 1946). Aminoglycoside antibiotics contain a core aminocyclitol ring attached to varying extents by saccharide units. The amino and hydroxy groups of the aminoglycosides react with the 16S rRNA in the 30S bacterial ribosomal subunit

Fig. 3 Chemical structure of antibiotics. (A) Major structural classes of β -lactam antibiotics. (B) Molecular structure of penicillin and D-Ala-D-Ala. (C) Streptomycin structure. (D) Tetracycline structure.

irreversibly through a network of hydrogen bonds (Fig. 3C). This arrests protein synthesis by interfering with the binding of **formyl-methionyl-tRNA** to the 30S subunit and renders the bacterium dysfunction. Resistance to aminoglycoside-based antibiotics occur mainly by enzymatic modification of drugs or the targets. The enzyme ribosomal methyltransferases modify the bacterial 16S rRNA subunit and confer aminoglycoside resistance particularly Gram-negative pathogens (Sharma et al. 2007).

Macrolides

The macrolides are the **polyketide** class of **naturally occurring compounds** with macrocyclic lactone ring containing eight or more atoms, and polyketide. Macrolides are generally bacteriostatic in that they suppress or inhibit bacterial growth rather than killing bacteria completely. **Erythromycin** was the first macrolide-based antibiotic discovered from a soil actinomycete *Saccharopolyspora erythraea* (Klein 1997). Clinically, macrolide drugs are most efficient against Gram-positive bacteria, but they also possess effectiveness against several Gram-negative, particularly upper respiratory tract pathogens. Macrolides react with the peptidyl transferase enzyme of the 50S ribosomal subunit, inhibiting protein-chain elongation. Active macrolide efflux is common in most Gram-positive pathogens. During the protein synthesis, the hydrophobic side of the macrolide molecule links to specifically the sidewall of the exit tunnel and leads to premature release of short peptidyl-tRNAs (Katz and Ashley 2005).

Tetracyclines

Tetracyclines are well known for their broad-spectrum of activity, spanning a wide range of Gram-positive and Gram-negative bacteria. They consist of a tetracyclic polyketide nucleus of fused six membered rings (Fig. 3D). Chlortetracycline and oxytetracycline were discovered in 1948 and 1950, respectively. Currently, they are isolated directly from various strains of *Streptomyces* or produced semi-synthetically from those isolated compounds. Tetracyclines block protein synthesis through binding reversibly to the bacterial 30S ribosomal subunit and interfere with the aminoacyl tRNA from binding to the A site of ribosome. Tetracyclines have also been found to inhibit matrix metalloproteinases (Connell et al., 2003).

The recent surveillance studies have revealed that the prevalence of resistance to tetracycline in certain European countries was detected to be 66.9% and 44.9% for extended-spectrum β -lactamase (ESBL) producing *Escherichia coli* and *Klebsiella* species (spp.), respectively (Jones et al. 2014). Similar results were found in another study by Mendes and colleagues that the global tetracycline resistance percentages were 24.3% and 8.7% for *Streptococcus pneumoniae*, and methicillin-resistant *Staphylococcus aureus* (MRSA) respectively (Mendes et al. 2015). Tetracycline resistance in Gram-negative bacteria is usually the result of active efflux pump, while in Gram-positive bacteria is through the acquisition of mobile genetic elements carrying tetracycline resistance genes, mutations within the ribosomal binding site, and/or mutations causing induced expression of intrinsic pathways (Jones et al. 2014).

Antimicrobial stewardship programs (ASPs)

Antimicrobial Stewardship Programs were implemented in healthcare settings for fighting bacterial antimicrobial resistance, improving guideline compliance, and lowering the use of broad-array antimicrobial agents. In 2017, the Joint Commission has developed standards for Antimicrobial Stewardship Programs for healthcare settings which were announced and put into action. The role of ASPs can be outlined as follows: to develop guidelines and protocols for proper use of antibiotics, restrict the use of antibiotics and raise awareness on misuse/overuse.

Most of developed and high-income countries including the US and European Countries, have implemented national programs as well as regulations to target antibiotic resistance; however, the emergency action plans should be implemented immediately particularly in low and middle income countries.

Conclusion

Currently, it is estimated that drug-resistant infections leads to over 700,000 deaths per year. In 2019, World Health Organization released a report stating that the deaths are calculated to upward to 10 million annually by 2050, exceeding the diseases of diabetes, heart disease, and cancer as the leading cause of death in humans, if it continues like this.

Globalization makes a significant contribution on the spread of antimicrobial resistance. Global trade, transportation and travel to distant destinations leads to spread resistant organisms more than ever before (Nordman et al., 2011). Social factors, the increasing number of nosocomial infections, and misuse/overuse of broad-spectrum antibiotics trigger the spread of pathogens. It is prominent that antimicrobial resistance is inevitable.

Alternative therapies may attenuate the selective pressure of antimicrobial chemotherapy. In fighting antimicrobial resistance, phage therapy and its products like lysin have become the center of interest again. Actually, the phage therapy has been used for a longer time than antibiotics in the combating against the bacteria, and they have proved to be high efficacy, selective, cost effective, and showing low toxicity and high tolerance (Twort 1915). A recent clinical study has shown that efficacy of phage therapy in the treating of various types of antibiotic resistant Gram-negative infections, suggests a comprehensive research is needed (Sulakvelidze et al., 2001). Researches on additional therapies such as immune stimulation, vaccination, topical agents, nanomaterials, prebiotics/probiotics are still ongoing (Renwick et al., 2016).

Undoubtedly, the vaccine development efforts on SARS-CoV-2 can help improve the vaccine therapy against antimicrobial resistant bacteria.

Glossary

α-Diversity Compositional diversity within a sample.

β-Diversity Compositional diversity between samples from the same habitat.

Biomarker Something that can be objectively measured to provide an indication of a biological process, whether normal or pathologic.

Colonization Presence of microbes on a surface.

Community state type Grouping of a community of microbes by phylotype composition and abundance.

Dysbiosis Alterations in the microbiota, usually with negative effects.

Fermentation Metabolic process that breaks down nutrients, may also refer to bioprocessing methods for microbial culture.

Genomics Study of the whole genomes of organisms, usually involving DNA sequencing and bioinformatics approaches in the analysis.

Gnotobiotic Environment where the microbial composition is well-defined, including germ-free conditions.

High-throughput screening Process for the automated testing of large numbers of samples.

Metagenome Combined genome of all the microbes in a community.

Microbiome Genetic content of the microbiota.

Microbiota Community of all the microbes living on or in a host.

Niche Environment where a microorganism can grow, including effects from nutrient availability, presence of competitors etc.

Operational taxonomic unit Species level classification system based on homology between reads for 16S rRNA profiling.

Organoid 3D structures with organ-like spatial organization for in vitro culture.

Probiotics Live microorganisms forming part of certain foods or supplements.

Introduction

The human microbiota is composed of all microbes, on the order of trillions, that live in or on the human body, including in the gut, oral and urogenital tracts, airways and placenta and on the skin and ocular surfaces. These microorganisms, including bacteria, viruses, fungi and protozoa, can be commensal, symbiotic or pathogenic. While microbes are often negatively associated with the concepts of infection and disease, the microbiota actually also plays an important role in maintaining the normal physiology and health of an individual, including influences on immune system function, metabolism and nutrition. The human microbiome, which encompasses the total genetic content of these microbes, is large and variable, especially when compared to the much more limited and substantially similar genetic makeup of humans. Thus, understanding the human microbiome (see [Table 1](#) for definitions of relevant terms) has become an interesting and challenging area of research. This article begins with a discussion of the Human Microbiome Project and its outcomes and continues with the structure and dynamics of healthy microbiota. After introducing state-of-the-art methods for appraising and studying the human microbiome in the laboratory, the second half of this article is focused on the dysbiosis of the microbiome and its connections with disease, particularly for the gut, oral, urogenital and skin microbiomes.

Table 1 Definition of relevant terms.

Term	Definition
α -Diversity	Compositional diversity within a sample
β -Diversity	Compositional diversity between samples from the same habitat
Biomarker	Something that can be objectively measured to provide an indication of a biological process, whether normal or pathologic
Colonization	Presence of microbes on a surface
Community state type	Grouping of a community of microbes by phylotype composition and abundance
Dysbiosis	Alterations in the microbiota, usually with negative effects
Fermentation	Metabolic process that breaks down nutrients, may also refer to bioprocessing methods for microbial culture
Genomics	Study of the whole genomes of organisms, usually involving DNA sequencing and bioinformatics approaches in the analysis
Gnotobiotic	Environment where the microbial composition is well-defined, including germ-free conditions
High-throughput screening	Process for the automated testing of large numbers of samples
Microbiota	Community of all the microbes living on or in a host
Microbiome	Genetic content of the microbiota
Metagenome	Combined genome of all the microbes in a community
Niche	Environment where a microorganism can grow, including effects from nutrient availability, presence of competitors etc.
Operational taxonomic unit	Species level classification system based on homology between reads for 16S rRNA profiling
Organoid	3D structures with organ-like spatial organization for in vitro culture
Probiotics	Live microorganisms forming part of certain foods or supplements

The human microbiome project (HMP) and healthy microbiota

Research on human microbiota can be found dating back to the 1960s (Schaedler et al., 1965; Rotimi and Duerden, 1981), but a major step forward was achieved through the Human Microbiome Project (HMP). The HMP was initiated by the National Institutes of Health (NIH, United States) in 2008, extending on the Human Genome Project. The goals of the HMP were to recruit at least 250 healthy individuals; sample microbiota from the skin, oral cavity, nasal cavity, gut and vagina; and ultimately to characterize the metagenome, combined from all these microbiomes, to determine the role of the human microbiome in both disease and healthy states (Aagaard et al., 2013). In theory, this would allow the association of the microbiome with variables such as disease, age, nutrition, medication and environment to be studied (The NIH HMP Working Group et al., 2009). The HMP was additionally expected to lead to technical advancements in bacterial culture, isolation of single microbial cells, purification of single species, and genomic amplification and cloning from single cells (The NIH HMP Working Group et al., 2009). Analytically, the HMP used a combination of taxonomic profiling by 16S ribosomal RNA gene sequences and whole genome shotgun sequencing to achieve metagenomics profiling (The NIH HMP Working Group et al., 2009). As outputs, it has provided collections of clinical samples and reference genomes, in addition to the analytical methods themselves (Méthé et al., 2012). The HMP was followed up by the Integrative Human Microbiome Project (iHMP) in a second phase from 2013 to 2016 with a focus on longitudinal studies of three more specific disease conditions: pre-term birth, inflammatory bowel disease (IBD) and type 2 diabetes mellitus (T2DM). In this project, the subjects were routinely sampled over a period of 3 years, and compositional and functional parameters of the their microbiomes were determined using sequencing and mass spectrometry techniques (The Integrative HMP (iHMP) Project Consortium, 2014).

The HMP has required that standardized 16S sequencing and analysis protocols be established (Méthé et al., 2012; Jumpstart Consortium Human Microbiome Project Data Generation Working Group, 2012), and these involve an operational taxonomic unit (OTU) based community structure. Amplification and sequencing is ideally performed on the same platform (Roche 454 FLX Titanium for the HMP), and a window covering 3–5 variable regions of the 16S rRNA gene is sequenced due to its utility in taxonomic classification (Méthé et al., 2012; Jumpstart Consortium Human Microbiome Project Data Generation Working Group, 2012). In bioinformatics analysis of the sequencing data, the raw read sequences are then preprocessed and denoised, assigned into a specific bacterial taxonomy using OTU databases and characterized in terms of diversity, often using Principal Coordinates Analysis (Caporaso et al., 2010; Moon and Lee, 2016). To increase the quality of the raw sequencing data, the 16S sequencing methods are regularly improved, such as through the low-error 16S rRNA amplicon sequencing method (Faith et al., 2013). Beyond 16S sequencing, next-generation sequencing may also play an important role in the identification of low abundance species and addressing issues such as short read problems (Malla et al., 2019). Metagenomic whole genome sequencing, or full shotgun metagenomics, not only allows for the same taxonomical profiling as 16S sequencing but also provides functional profiles of the microbial communities through assembly of the raw read sequences, gene prediction and functional annotation (Moon and Lee, 2016).

Within the HMP, an open-source platform called mothur was developed as part of the data processing pipeline (Schloss et al., 2009). The generation of vast amounts of data from the HMP and iHMP, as well as from other studies on the human microbiome, has required the integration of computational modeling approaches, as well as their associated methodological advancements, into human microbiome research (Chowdhury and Fong, 2020). These techniques have been used to extend the genomic information to make predictions of function, for example through the use of ancestral-state reconstruction algorithms (Langille et al., 2013) or

genome-scale metabolic modeling, which can provide information on microbe-microbe and host-microbe interactions (Thiele and Palsson, 2010; Gu et al., 2019). One of the largest genome scale metabolic models, with 773 gut bacteria, has been used to predict nutrient requirements for the development of chemically defined medium (Magnúsdóttir et al., 2017). Other computational approaches, such as deep neural network interpretation algorithms, have been used to explain the contribution of features of the microbiome data on disease characteristics, as has been done to classify insulin resistance vs. sensitivity on data coming out of the iHMP, although only consideration of multiple features could sufficiently classify the samples (Huang et al., 2021b).

A main outcome of the HMP was to confirm that the microbiome differs a lot, even among healthy individuals. For example, among the different sites sampled, the oral and stool samples had the greatest compositional diversity, whereas the samples from the vagina had the least (Huttenhower et al., 2012). Further analysis showed that, despite variations in composition, the metabolic pathways were often stable among individuals (Huttenhower et al., 2012). Details on the composition of the gut, skin, oral and urogenital microbiomes, of which some information has originated in the HMP, are provided later in this article. The iHMP has led to resources, such as the Inflammatory Bowel Disease Multi'omics Database, as well as insights into the dysbiosis of the gut microbiome in IBD. For example, facultative anaerobes were shown to increase while obligate anaerobes decreased, and disturbances in microbial transcription, metabolite pools and antibody levels in host serum were observed (Lloyd-Price et al., 2019).

Even among healthy individuals, there is a wide variation in the composition of the human microbiota. A concept that has been put forward is a "functional core," which characterizes the healthy microbiota by its metabolic and molecular functions rather than by the specific composition of microorganisms (Bäckhed et al., 2012; Shafquat et al., 2014). In this way, the collection of genes and pathways is more important than the specific microbes that are present (Bäckhed et al., 2012), and the functional niche can be filled with different microbial compositions (Shafquat et al., 2014). Thus, in addition to the normal microbes, their function, ecological properties (diversity of taxa present), and temporal dynamics are important to characterize healthy human microbiota (Lloyd-Price et al., 2016). These functions are related to the microbes themselves, such as transcription, translation, and energy production; to host-microbe interactions, such as adhesion and production of vitamins and immunostimulatory compounds; and to specific sites, such as glycosaminoglycan degradation and short-chain fatty acid production in the gut (Lloyd-Price et al., 2016). Thus, integration of the microbiome with metabolic models is critical to understand the mechanisms linking the microbiome to healthy and diseased states (Sung et al., 2016; Noecker et al., 2015).

State-of-the-art methods for appraising the human microbiome

In vitro cell culture offers a convenient approach to study different cellular processes and to probe mechanisms of disease; however, the complexity of the human microbiota has been difficult to replicate using traditional cell culture methods. Sometimes referred to as synthetic gut microbial ecosystems, these in vitro systems still only involve the culture of limited numbers of bacterial strains and start from traditional batch as well as multi-stage continuous fermentation culture systems (Vrancken et al., 2019). Emerging technologies for three dimensional (3D) in vitro tissue models, such as organ-on-chip devices and organoid cultures, are being developed, and these have started to be applied to the study of the human microbiota. The most advanced systems replicate key features of the gut microbiota, and in vitro models of the skin (Niehues et al., 2018) and oral cavity have also been developed, such as human callus as a substrate for skin pathogens (van der Krieken et al., 2016) and mixed fungal-bacterial oral biofilms (Chevalier et al., 2018). Further, gnotobiotic animal models have been developed to study the human microbiota in vivo, although certain physiological and metabolic limitations do exist.

Organoids are an emerging technique that has been developed in the last decade or so for the 3D culture of primary cells, typically adult stem cells or pluripotent stem cells, in a microscale structure that mimics the natural organization of cells within a tissue. A key aspect of organoids is that they can be established with an individual's cells and thus can be used to determine patient-specific responses. Some of the first organoids were developed by Sato et al., who used intestinal derived cells that self-organized into crypt and villus structures (Sato et al., 2009). Of relevance to the human microbiota, organoids have been used as in vitro models for infection with *Helicobacter pylori* (*H. pylori*) and *Salmonella enterica* (*S. enterica*) as well as for studying gut-microbiota interactions and diseases like IBD and cancer, as recently reviewed (Bartfeld, 2016; Almeqadi et al., 2019). Some of the most advanced work with organoids for modeling infectious disease has been performed with the bacteria *H. pylori* in gastric organoids. As these organoids form spherical structures with a lumen where the apical side of the cell is on the inside, *H. pylori* have been injected into this lumen and have been shown to adhere to the epithelium (Bartfeld et al., 2015) as well as cell-cell junctions (Huang et al., 2015) and further to be able to proliferate in the organoid microenvironment (Bertaux-Skeirik et al., 2015). Similarly, human intestinal organoids have supported the replication of rotavirus (Finkbeiner et al., 2012) and have been used to study norovirus infection and the role of bile in its replication (Ettayebi et al., 2016) as well as the invasiveness of *S. Typhimurium* across the epithelial barrier (Forbestor et al., 2015; Zhang et al., 2014). Further, human intestinal organoids have been used to show that toxic *Clostridioides difficile* strains act by disrupting the epithelium and its paracellular barrier function (Leslie et al., 2015).

Human microphysiological models of the intestine or so-called intestine-on-chip devices are a recently developed technology that have relevance for the study of the gut microbiome. These systems typically rely on microfabrication techniques and microfluidics to build up and maintain more complex 3D tissue models. These types of models of the intestine have been used more broadly in the study of nutrition, inflammation and cancer (Steinway et al., 2020) and have potential in drug discovery and personalized medicine approaches (Bein et al., 2018). Moreover, they have begun to be used in the study of the microbiome. A microfluidic device with a flexible membrane has been used to examine the effects of peristalsis on bacterial overgrowth as well as to

mimic inflammatory conditions that can disrupt intestinal barrier function (Kim et al., 2016), and another type of microfluidic device has been utilized to replicate the intestine-microbe interface, using the commensal anaerobic bacteria *Lactobacillus rhamnosus* GG, for insight into transcriptional, metabolic and immunological responses (Shah et al., 2016). Interestingly, systems that can establish oxygen gradients can be used to co-culture anaerobic bacteria with human intestinal cells (Jalili-Firoozinezhad et al., 2019; Kim et al., 2019). The oxygen gradients have allowed one in vitro system to support a high level of microbial diversity (>200 unique OTUs) as well as increased intestinal barrier function (Jalili-Firoozinezhad et al., 2019) whereas another supported both facultative and obligate anaerobes in its luminal compartment and promoted a more biomimetic crypt architecture (Kim et al., 2019).

Animal models are primarily used in biomedical research to gain understanding of disease mechanisms and to develop and/or test treatment options. Interestingly, *Drosophila melanogaster* has been used as a model system to study the influence of host genotype on gut microbiota abundance and its effect on nutritional status (Chaston et al., 2016). Conventional mouse models have been utilized, for example, to study the effects of genotype on the composition of gut microbiota and sensitivity to colitis; however, these models typically require the study of littermates (Lemire et al., 2017). Gnotobiotic rodent models, including germ-free models, have been used to study host-microbe interactions (Smith et al., 2007). They can also be useful in nutrition research. For instance, gnotobiotic mice, which were colonized with fecal microbiota from a human donor, were used to study the link between sialylated milk oligosaccharides, the gut microbiota and healthy growth, as this promotion of growth did not occur in germ-free mice (Charbonneau et al., 2016). However, rodent models may not sufficiently replicate the (patho)physiological and metabolic processes of humans. Therefore, increasing attention has turned to swine models (Heinritz et al., 2013; Lunney, 2007), including human microbiota-associated swine, which are established through inoculation with gut microbiota from human donors (Wang and Donovan, 2015).

Gut microbiome at the intersection of health and disease

As our largest and richest reservoir of microorganisms, the human gut microbiota represents a densely populated and diverse microbial community outnumbering even our cells, and it is estimated to harbor over 1000 different bacterial species, as well as commensal fungi, viruses and archaea (Qin et al., 2010; Meštrović, 2016). More than 90% of the species comprising normal human gut microbiota belong to four principal bacterial phyla—Firmicutes, Bacteroidetes, Actinobacteria and Proteobacteria; furthermore, three leading genera have been reported as enterotypes of the human gut—*Bacteroides*, *Ruminococcus*, and *Prevotella* (Ley et al., 2008; Arumugam et al., 2011; Matijašić et al., 2020). Dietary habits of the host and phylogeny additionally contribute to such protean composition of intestinal microbial communities in humans and other mammals (Liang et al., 2018; Yu et al., 2021).

Compositional and functional changes of the intestinal microbiome are omnipresent in various forms of IBD, including ulcerative colitis (UC) and Crohn's disease (CD) (Mar et al., 2016; Schirmer et al., 2018). The use of sequencing methods has established the presence of significant differences in the gut microbiome of IBD patients in comparison to that of healthy individuals, with decreased diversity and bacterial load (the latter being touted as a potential biomarker in IBD) (Matijašić et al., 2016; Sarabayrouse et al., 2021). More specifically, individuals with UC and CD demonstrate a reduction in Firmicutes (especially *Clostridium* groups) and an increased abundance of Proteobacteria (Manichanh et al., 2006; Frank et al., 2007). However, a notable finding is a significant decline of protective bacterial species belonging to genera such as *Bacteroides*, *Lactobacillus* and *Eubacterium* (Matijašić et al., 2016; Mullish et al., 2021). In regards to fungal dysbiosis in IBD, there is higher Basidiomycota/Ascomycota ratio, an increased abundance of *Malassezia sympodialis* and *Candida albicans*, as well as lower numbers of *Saccharomyces cerevisiae* (Sokol et al., 2017). Fungal-bacterial interactions, as determined by functional modeling, are higher in patients with UC than CD (Sokol et al., 2017).

The gut microbiota has been recently recognized as a paramount mediator of biochemical signaling and intercommunication between the gastrointestinal tract and the central nervous system, which is frequently referred to as the gut-brain axis (Cryan et al., 2019) (Fig. 1). Consequently, a plethora of behavioral disorders have been linked to perturbed intestinal microbiota, including autism spectrum disorder (ASD) in children (Iglesias-Vázquez et al., 2020). More specifically, the microbiota in children with ASD shows increased bacterial diversity and higher abundance of genera *Bacteroides*, *Clostridium*, *Collinsella*, *Corynebacterium*, *Faecalibacterium*, *Lactobacillus*, *Parabacteroides*, *Phascolarctobacterium* and the fungal pathobiont *Candida* in comparison with controls, while there is a depletion of *Bifidobacterium* and *Coprococcus* (Iglesias-Vázquez et al., 2020; Strati et al., 2017). Recent studies have also shown that the gut microbiome is an important factor in diseases such as Alzheimer's disease, Parkinson's disease and stroke, primarily due to the production of modulatory neuroactive compounds (Benakis et al., 2020; Kesika et al., 2021).

T2DM is a major public health concern that may be linked to the composition of the intestinal microbiota, as even prediabetic conditions, such as incipient insulin resistance, are increasingly related to gut dysbiosis (Roager et al., 2019; Salgado et al., 2019). The main traits of the microbiota in patients with T2DM are decreased concentrations of butyrate-producing bacteria, most notably *Faecalibacterium prausnitzii* and *Roseburia intestinalis* (Sabatino et al., 2017), as well as lower prevalence of Firmicutes. There is also an increased prevalence of *Betaproteobacteria* family and opportunistic pathogens (e.g., various species of the *Clostridium* genus, *Eggerthella* spp. and *E. coli*) (Roager et al., 2019; Salgado et al., 2019; Larsen et al., 2010). The condition is also intertwined with obesity, as substantially reduced bacterial complexity is observed in both conditions. Especially evident is a decrease in *Bacteroides*/*Prevotella* groups and the *Bacteroidetes* phylum (Andoh et al., 2016; Indiani et al., 2018). However, although there are various probiotic formulations proposed to tackle both T2DM and obesity (Tseng and Wu, 2019), we have to be cognizant of the fact that these conditions are complex and multifactorial, and thus have to be addressed from different angles.

Fig. 1 A schematic diagram of bi-directional communication of intestinal microbiota with the central nervous system (also known as the “gut-brain axis”).

Some recent studies have emphasized the significance of the gut microbiome in modulating responses to different types of cancer immunotherapy (Roy and Trinchieri, 2017; Zitvogel et al., 2018). Patients with malignant diseases who respond well to treatment with anti-programmed cell death protein 1 basically have much more diverse gut microbiomes when compared to non-responders (Gopalakrishnan et al., 2018). The latter group presents with a low abundance of microorganisms belonging to the genera *Akkermansia*, *Bifidobacterium* and *Faecalibacterium* (Gopalakrishnan et al., 2018; Matson et al., 2018). At the phylum level, patients with an abundance of Firmicutes and Verrucomicrobia generally have a better response when immune checkpoint inhibitors are used, unlike those with increased numbers of Proteobacteria (Huang et al., 2021a).

Many chronic diseases associated with the alteration of intestinal microbiota are increasingly being tackled by a promising approach known as fecal microbiota transplantation (FMT) (Dixit et al., 2021). However, the effectiveness and safety of manipulating gut flora with the use of donor feces has been established only for recurrent *Clostridioides difficile* infection recalcitrant to antimicrobial treatment (Quraishi et al., 2017). FMT is usually delivered either directly to the large bowel or from the upper gastrointestinal tract by capsule ingestion (Gweon and Na, 2021), and engraftment can be facilitated by controlling inflammation in the recipient intestine, as it reduces the host immune response against the transplant (Danne et al., 2021). Recently, a specific ecological framework was proposed recognizing the efficacy of FMT in various conditions that have a common trait of disrupted intestinal microbiota, and several crucial factors were highlighted that determine its success, most notably host-dependent microbial dynamics and pre-FMT taxonomic diversity (Xiao et al., 2020). This has opened a door to developing an algorithm for designing personalized probiotic cocktails as a way towards a true precision medicine approach—with future microbiota-based therapeutics that hold a promise in ameliorating the aforementioned chronic conditions.

Oral microbiome and periodontal diseases

The oral microbiome, recently called the “oralome,” is characterized by notable shifts during the life time—from incipient bacterial acquisition after birth to microbial colonization of the elderly (Radaic and Kapila, 2021; Krishnan et al., 2017). This is an important niche, since the oral cavity harbors the second largest and most variegated microbiota with more than 700 bacterial species, which is surpassed only by the intestines (Deo and Deshmukh, 2019). In health, the oral microbiome can be viewed as a dynamic, but incredibly balanced, ecosystem that tends to stay within typical frames of equilibrium (Najmanova et al., 2021). Furthermore, compositional patterns of the oral microbiome vary in terms of optimal equilibrium of this microbial community, primarily in regards to geography, which are referred to as “stomatotypes” in the current literature (Willis et al., 2018; Willis and Gabaldón, 2020).

One of the most pervasive human bacterial infections is dental caries, which results often in tooth decay and potentially in the loss of teeth (Zhang et al., 2021). Among the main etiological factors is frequent sugar intake, which prompts commensal bacteria to adjust to the resultant acidic milieu, accommodating in turn the growth of aciduric bacterial species and inhibiting the beneficial microorganisms that favor neutral pH values (Radaic and Kapila, 2021). Although *Streptococcus mutans* (*S. mutans*) is the hallmark bacterial species implicated in this condition and often referred to as the “core-pathogen,” molecular methods, such as microarrays or the well-established 16S rRNA approach, have revealed that carious lesions additionally harbor high amounts of species

belonging to the genera *Atopobium*, *Lactobacillus* and *Cutibacterium* (Aas et al., 2008; Zheng et al., 2021). However, there are even cases of dental caries with no detectable levels of *S. mutans*, when there is an abundance of *Actinomyces* spp., *Bifidobacterium dentium*, *Lactobacillus* spp., *Scardovia* spp., *Veillonella* spp. and non-*S. mutans* species of streptococci (Zhang et al., 2021). A shift in the composition of the tongue microbiota is also significantly linked to dental caries, as evidenced in a study on primary school children (Zhang et al., 2021).

Unlike dental caries, the etiology of periodontitis still cannot be explained by a single hypothesis. This is one reason why knowledge about the inception of periodontal diseases and the microorganisms that drive the condition known as periodontitis remains scarce, despite decades of scientific work on this topic (Rosier et al., 2014). In comparison to the healthy periodontal state, periodontitis—which is a multifactorial inflammatory disease that results in the loss of periodontal attachment and alveolar bone—shows increased microbial diversity driven by a rich interaction profile with genetic and environmental factors within specific time windows (Na et al., 2021). Consequently, as each patient has a different constellation of colonizing microorganisms and internal/external risk factors, the pathogenesis of periodontitis can be viewed as a personalized pathological condition characterized by specific tissue-destructive outbursts (Scannapieco and Dongari-Bagtzoglou, 2021).

Bacterial taxa substantially more prevalent and abundant in periodontal diseases primarily encompass so-called red complex bacteria: *Porphyromonas gingivalis*, *Tannerella forsythia* and *Treponema denticola* (Socransky et al., 1998). In addition, there is also a notably higher prevalence of species belonging to the genera *Desulfobulbus*, *Fretibacterium* and *Peptostreptococcus*, as well as *Filifactor alocis* and *Selenomonas sputigena* (Curtis et al., 2020; Szafranski et al., 2015; Shi et al., 2015; Najmanova et al., 2021). Researchers have also discovered additional species that are not habitually found in periodontal disease, including *Brevundimonas diminuta*, *Dialister invisus*, *Granulicatella adiacens*, *Mycoplasma salivarium*, *Pseudoramibacter alactolyticus*, *Shuttleworthia satelles* and *Veillonella atypica* (Krishnan et al., 2017). A notorious and multiresistant nosocomial pathogen *Acinetobacter baumannii* has also been recognized as a salient risk factor for periodontitis refractory to treatment (Richards et al., 2015).

Conversely, only a handful of taxa have been unequivocally linked to periodontal health, most notably species belonging to the genera *Actinomyces* and *Streptococcus* (Griffen et al., 2012; Abusleme et al., 2013; Kirst et al., 2015; Meuric et al., 2017). Likewise, for many bacterial taxa the exact classification between periodontal health and disease has proven to be a very cumbersome exercise, as they commonly display matching prevalence and relative abundance in both of these states. These include, but are not limited to, very abundant members of the genus *Streptococcus*, *Fusobacterium nucleatum* and *Veillonella parvula* as well as infrequently recognized *Campylobacter gracilis*, *Granulicatella adiacens* and *Lautropia mirabilis* (Abusleme et al., 2013; Tsai et al., 2018). Still, dysbiosis is dependent not only on the taxonomic composition of the oral microbiome but also on its metabolic activity and the subsequent host response to microbial products (Lenartova et al., 2021).

Even though the purported connections are based on correlations, altered oral microbiota has been repeatedly observed to have an effect in various diseases outside the oral cavity, such as bacteremia, endocarditis, diabetes, autoimmune diseases, malignancies and even preterm births (Verma et al., 2018). Hence, extensive profiling of oral microorganisms from healthy individuals will be pivotal for further comparisons under dysbiotic conditions. This is where massive sequencing with the use of third generation next-generation sequencing (NGS) techniques will be crucial to establish oral microbial databases for tailored, microbiome-based treatments in the future. For example, the PacBio single-molecule real-time (SMRT) sequencing platform was already used to survey biomarkers of microbiome dysbiosis in the oral cavity of elderly patients with Alzheimer's disease (Wu et al., 2021). All of these advances are opening the door for promising personalized dentistry approaches.

Urogenital microbiome and genitourinary pathology

The microbiome of the human urogenital tract is complex and diverse, which is especially evident in the female vagina. More specifically, the vaginal microbiome is dominated by several varieties of lactobacilli that maintain homeostasis. Nonetheless, high-throughput sequencing endeavors addressing bacterial abundance in the female genital tract have demonstrated that factors such as hygiene practices, hormones and sexually transmitted infections may disrupt the natural balance, resulting in the outgrowth of some bacterial groups and subsequent pathology (such as bacterial vaginosis, recurrent infections in the urinary tract and tumor-promoting effects) (Ravel et al., 2011; Chen et al., 2021). Five community state types (CSTs) of the vaginal microbiome are recognized. CST I, II, III and V are characterized by low microbial diversity and are dominated by *Lactobacillus crispatus* (*L. crispatus*), *Lactobacillus gasseri* (*L. gasseri*), *Lactobacillus iners* (*L. iners*) and *Lactobacillus jensennii* (*L. jensennii*), respectively (Chen et al., 2021). Conversely, in CST IV, there is a reduced number of lactobacilli and high diversity of primarily anaerobic bacteria, which are frequently linked to bacterial vaginosis (Ravel et al., 2011).

Bacterial vaginosis represents a very common lower genital tract disorder affecting women of reproductive age around the world (Javed et al., 2019). It is characterized by the loss or a marked reduction in the total number of *Lactobacillus* species, as well as a commensurate 100–1000-fold rise in the abundance of obligate and/or anaerobic microorganisms that belong to the genera *Gardnerella*, *Atopobium*, *Prevotella*, *Bifidobacterium*, *Mobiluncus*, *Leptotrichia* and *Sneathia* as well as certain novel constituents of the order *Clostridiales* designated as bacterial vaginosis-associated bacteria (BVAB) 1–3 (Fredricks et al., 2005; Srinivasan et al., 2012; Muzny et al., 2018; Chen et al., 2021). One of the key facets in the pathogenesis of bacterial vaginosis is the development of polymicrobial biofilms instigated by *Gardnerella vaginalis* (*G. vaginalis*) that form a scaffold for the attachment of other microorganisms, such as *Atopobium vaginae* as a second colonizer (Hardy et al., 2017; Jung et al., 2017).

Moreover, different studies have shown that women with a low abundance of lactobacilli are more frequently colonized with vaginal *E. coli* than those with lactobacilli-dominated microbiomes, which consequently modulates the risk of the development of urinary tract infections (UTIs) (Gupta et al., 1998; Lewis and Gilbert, 2020; Meštrović et al., 2021). Different species of lactobacilli, but predominantly *L. crispatus*, have the proclivity to inhibit the growth of *E. coli*, primarily by establishing and preserving a low pH environment (Hudson et al., 2020; Vagios et al., 2020). In addition, multiple studies in both non-pregnant and pregnant women have demonstrated that bacterial vaginosis can increase the risk of microbial colonization in the vaginal introitus and subsequent UTI (Harmanli et al., 2000; Stapleton et al., 2011; Amatya et al., 2013).

Although the penile microbiome remains understudied, men can also play a considerable role in bacterial vaginosis, as the urethral meatus and coronal sulcus of the penis are salient reservoirs of associated bacteria in both uncircumcised and circumcised men (Onywera et al., 2020). More specifically, bacterial species from these penile regions have high predictive power for incident bacterial vaginosis that is seen up to 6–12 months later in their female sex partners (Mehta et al., 2020). Further, although penile *Staphylococcus* and *Corynebacterium* species have been linked to healthy microbiomes of the cervix and vagina and they notably increase after male circumcision, additional investigation is necessary in order to establish their exact roles in the reproductive health of both men and women (Onywera et al., 2020).

The acquisition of sexually transmitted infections (STIs) is also linked to urogenital microbiome disruption. The most researched STI is human immunodeficiency virus (HIV), which is associated with certain bacterial taxa. More specifically, the abundance of *Prevotella* spp., *Parvimonas* spp. type 1 and type 2, *Veillonella montpellierensis*, *Eggerthella* spp. type 1, *Mycoplasma* spp., *Gemella asaccharolytica*, *Sneathia sanguinegens* and vaginal *Megasphaera* spp. significantly correlate with increased HIV acquisition (Gosmann et al., 2017; McClelland et al., 2018). The propensity of the aforementioned bacterial taxa to instigate a vigorous inflammatory response in the cervicovaginal milieu—with the subsequent recruitment of CCR5⁺ CD4⁺ T cells (the primary cells targeted by HIV) and increased concentrations of interleukins (most notably IL-1 β , IL-17 and IL-23)—are key pathophysiological mechanisms (Gosmann et al., 2017; Torcia, 2019). In men, the subpreputial space harbors a rich community of anaerobic bacteria and is a proinflammatory immune milieu, which purportedly enables the acquisition of HIV, but thus far studies on the topic are very scarce (Onywera et al., 2020).

In women, certain dysbiotic bacterial communities may result in immune dysregulation that favors a tumor-promoting microenvironment and influences whether cervical precancerous lesions will regress or progress to cancer (Schwabe and Jobin, 2013; Garrett, 2015). Accordingly, human papillomavirus (HPV) is an essential, but not sufficient prerequisite of cervical cancer, which is reinforced by the fact that in the majority of infected women the immune response controls the infection and fends off high-grade lesions and tumors (Insinga et al., 2011; Castanheira et al., 2021). Hence, vaginal microbiota may well be one of the more important co-factors in the development of cervical cancer, especially when lactobacilli are concerned (Castanheira et al., 2021; Kwasniewski et al., 2018). In instances when *L. crispatus* predominates, there is generally a lower risk of HPV infection, cervical intraepithelial neoplasia (CIN) and cervical carcinoma, whereas a predomination of *L. iners* increases those risks (Norenhag et al., 2020). In addition, the presence of *Gardnerella vaginalis* and an increase in microbiological diversity may be viewed as biomarkers of changes in the cervix to recognize women with higher risks of persistent HPV infection, CIN and subsequent cancer development (Usyk et al., 2020).

Finally, the urinary microbiome should not be neglected, and its role is not only suggested in manifold pathologies of the urinary system, such as overactive bladder (Wu et al., 2017), urge incontinence (Pearce et al., 2014) and urothelial carcinoma (Bučević Popović et al., 2018), but also in the pathogenesis of UTIs (Meštrović et al., 2021). Regarding the latter, two pivotal studies in this field showed that individuals who are prone to developing UTIs present with lower diversity of the urinary microbiome (Horwitz et al., 2015) and that its perturbations basically precede the UTI development (Bossa et al., 2017), implying that the whole condition can be viewed as a “urinary tract dysbiosis” (Finucane, 2017). However, additional longitudinal appraisal of the urinary microbiome in different pathological conditions is warranted before any steadfast conclusions can be drawn.

Skin microbiome and dermatologic conditions

Adequate comprehension of the microbial composition found on healthy human skin is indispensable for establishing a reference state and subsequently detecting changes linked to certain skin diseases. In contrast to the intestines, which are almost an optimal environment for fermentative bacterial species, the skin represents an inhospitable area due to the dry, acidic, salty and nutrient-deficient epidermal layer, with the exception of lipid-rich havens around hair follicles (Ellis et al., 2019). In healthy individuals, the skin microbiota is responsible for mediating fundamental physiological processes including epidermal development and differentiation as well as underlying immune responses (Nørreslet et al., 2020). Consequently, inflammatory and other skin diseases, such as atopic dermatitis, seborrheic dermatitis, acne vulgaris, rosacea, hidradenitis suppurativa and psoriasis, are characterized by condition-specific changes of the microbial composition and subsequent dysbiosis.

There are four dominant phyla that comprise the skin microbiome: Actinobacteria, Bacteroidetes, Firmicutes and Proteobacteria (Grice et al., 2009). Although there is ample diversity among individuals, with various topographic niches, this microbiome is relatively stable over time (Grice et al., 2009; Oh et al., 2016; Nørreslet et al., 2020). Three principal categories of skin habitats are designated as (1) dry (such as the hand and the forearm) where β -proteobacteria, *Corynebacteriaceae* and *Flavobacteriales* are found; (2) moist (such as the axilla) where species of the genus *Staphylococcus* are pervasive alongside β -proteobacteria and *Corynebacteriaceae*; and (3) sebaceous (such as the forehead) where *Staphylococcus* and *Cutibacterium* (formerly known as *Propionibacterium*) tend

to dominate (Grice et al., 2009). Areas with the most diverse microbiome according to bacterial operational taxonomic units are dry, while sebaceous regions harbor the least diverse microbial communities (Nørreslet et al., 2020).

In atopic dermatitis (AD), which is a chronic allergic skin condition also known as eczema, the microbiome is characterized by a state of dysbiosis with diminished bacterial diversity (α -diversity) and decreased stability over time (Kong et al., 2012). Importantly, this is coupled with persistent colonization by *Staphylococcus aureus* (*S. aureus*), which also positively correlates with the severity of AD lesions (Byrd et al., 2017; Clausen et al., 2018). Furthermore, it has been demonstrated that infants harboring *Staphylococcus epidermidis* (*S. epidermidis*) and *Staphylococcus cohnii* at 2 months of age have a reduced risk of developing AD by 1 year of age due to increased microbial diversity (Kennedy et al., 2017) whereas *S. aureus* colonization actually precedes the clinical diagnosis of AD in infancy (Meylan et al., 2017).

Seborrheic dermatitis (SD) represents a common inflammatory rash that appears on skin areas laden with sebaceous glands and is frequently linked to the fungal genus *Malassezia*. This fungus is viewed as a normal constituent of the human skin microbiota, albeit its exact role in the development of SD is still inadequately understood (Luciana Campos, 2017). Recent studies have shown that certain bacterial species dominate in the lesioned skin and are implicated in SD development, especially *Staphylococcus*, *Streptococcus* and *Acinetobacter* (Tanaka et al., 2016). Another cohort study demonstrated that individuals with SD have higher numbers of colonizing *S. epidermidis* in comparison to those without the condition (An et al., 2017).

Cutibacterium acnes (*C. acnes*) is believed to be an important player in the pathogenesis of acne vulgaris; nonetheless, the causal relationship is still unclear (O'Neill and Gallo, 2018), especially since this species is found in healthy individuals and prevents colonization with opportunistic pathogens (Nørreslet et al., 2020). A deeper dive into the phylogenetic clades shows an association between *C. acnes* strain IA-2 and acne vulgaris (Kasimatis et al., 2013; McDowell et al., 2013), so this relationship may be strain-specific. This is further supported by the findings from a metagenomic study where an imbalance of virulent *C. acnes* has been noted (Barnard et al., 2016). Moreover, several studies have shown that *S. epidermidis* is more abundant in active acne lesions (Nishijima et al., 2000; Bek-Thomsen et al., 2008; Dreno et al., 2017), although one study showed that *S. epidermidis* may have a beneficial effect in acne lesion recovery (Pathak et al., 2013).

The cutaneous microbiome of patients with rosacea, which is a common long-term inflammatory condition of facial skin, has been a subject of many studies (Kim, 2020). A lot of them focused on the commensal mite *Demodex folliculorum*, as its prevalence and density are much higher in rosacea-affected skin in comparison to unaffected controls (Kim, 2020). It has been suggested that the mite exacerbates the disease by influencing the immune reactivity of sebocytes, triggering activation of the TLR2 signaling pathway and disrupting the skin barrier (Lacey et al., 2018). *Demodex* mites are also probable carriers of *Bacillus oleronius*, which is a Gram-negative bacterial species with proinflammatory potential (Picardo and Ottaviani, 2014). In addition, a beta-hemolytic variant of *S. epidermidis*, which possibly exerts increased virulence traits, was isolated from rosacea patients (Dahl et al., 2004; Whitfeld et al., 2011). Furthermore, *C. acnes* plays a substantial role in rosacea, and it may even have a beneficial effect (Jahns et al., 2012; Kim, 2020).

Even though the clinical presentation of hidradenitis suppurativa points towards a bacterial infection, the exact role of the cutaneous microbiome has been controversial; however, some recent studies reveal a purported link between skin microbiome dysbiosis and this condition (Wark and Cains, 2021). Significant differences between patients with hidradenitis suppurativa and healthy individuals were demonstrated on the genus and species levels with the use of next generation sequencing (Ring et al., 2017; Ring et al., 2019). The dominant species in the diseased lesions were from the genera *Peptoniphilus*, *Porphyromonas* and *Corynebacterium* as well as *Campylobacter ureolyticus*, *Actinomyces* and *Mobiluncus* (Ring et al., 2017; Riverain-Gillet et al., 2020). On the other hand, controls did not harbor *Peptoniphilus* at all, and *Cutibacterium* was more abundant in controls (Ring et al., 2017; Wark and Cains, 2021).

Psoriasis, a skin disease characterized by scaly and erythematous plaques, is also coupled with changes in the cutaneous microbiome when compared with healthy controls, most notably as a significant decrease in microbiome α - and β -diversity (Olejniczak-Staruch et al., 2021). More specifically, there is a decrease in Actinobacteria and an increased abundance of Firmicutes in psoriatic lesions, which can be reversed after systemic treatment with antibiotics (Langan et al., 2019). And even though psoriasis is rarely aggravated by a clinical superinfection, a higher relative abundance of staphylococcal and streptococcal species was observed in psoriatic lesions when compared to non-lesioned skin (Lewis et al., 2019). Some studies even highlight the role of *Candida albicans* in psoriasis pathogenesis due to induction of interleukin-36 α production and subsequent psoriasiform phenotype development (Hashiguchi et al., 2018).

In conclusion, skin disease development can be observed as an intricate interplay between genetic predisposition, the local immune system and the composition of microbiome, as increasing evidence points towards the last as a pivotal element. Potentially, strains of microbial species deemed as beneficial may be utilized in the future to evade dysbiosis, and consequently to improve or treat underlying skin disorders. The improved understanding of the cutaneous microbiome may also translate into novel diagnostic and preventative approaches in the context of personalized or precision medicine.

Conclusion

It is clear that the human microbiota represents a tremendously complex, but at the same time an extremely well organized, community of microorganisms. With the use of state-of-the-art techniques, today we are becoming increasingly aware not only of all crucial constituents of the healthy human microbiome, together with their functional roles, but also of the shifts that lead to

dysbiosis and have a role in specific diseased states. Further research into functional host-microbiome interactions is warranted to elucidate all interactions that can lead to disease, which will in turn result in precision medicine approaches targeting microbiota in order to maintain homeostasis and health. The ultimate objective of human microbiome research is always translational in nature—to optimize health and disease management.

Glossary

Microbiome The collective genomic content of the microbiota and also indicates the total genetic capacity of the community.

Microbiota The collective microbial community inhabiting a specific environment. Cellular density increases along the length of the gut, and the colonic microbiota are the densest and most diverse community in both the gut and whole human body.

Prebiotics First defined in 1995 (Gibson and Roberfroid, 1995), are used to manipulate microorganisms in the host to improve measurable outcomes. An update to the definition of prebiotics was published in 2017 as “a substrate that is selectively utilized by host microorganisms conferring a health benefit” (Gibson et al., 2017). Prebiotic effects include defense against pathogens, immune modulation, mineral modulation, mineral absorption, bowel function, metabolic effects, and satiety (Sanders et al., 2019; Roberfroid et al., 2010).

Probiotics Defined as live microorganisms that, when taken in a sufficient amount, have a benefit for the ingesting host (FAO and WHO, 2002). Probiotic microorganisms act via a variety of means, including modulation of immune function, the production of organic acids and antimicrobial compounds, interaction with resident microbiota, interfacing with the host, improving gut barrier integrity, and enzyme formation (Sanders et al., 2019).

The human gut microbiota

Recent studies have shown that the trillions of microbes that inhabit our gut form a complex ecological community that influences our health and can account for the incidence of various diseases. Understanding the factors that underlie changes in the composition and function of the gut microbiota will aid in the development of clinical applications. Although the beneficial effects of some microbes have been documented for more than a century, only with recent technological advances can the composition of the diverse microbial communities be described and compared with and between individuals. Currently for clinical applications, probiotics and prebiotics are used.

The microbial colonization of the human gut begins immediately at birth and is an indispensable natural process that modulates physiology and immunity. Recent studies have revealed how and when these microbes colonize the gut and what elements can potentially influence it. The vertical mother-to-baby transmission of microbes is a crucial factor for normal development and the maturation of a newborn's immune system, as well as metabolic and neurological health. This important and delicate process of gut microbiota development may be impacted by various factors such as the mode of birth, type of feeding, gestational age at birth, antibiotic exposure in early life, and the surrounding environment and hygiene settings. Perturbations in early life gut microbial colonization have been associated with the development of several diseases such as diabetes, obesity, asthma, allergies, celiac disease, and neurodevelopmental disorders (Nagpal and Yamashiro, 2015). Babies born vaginally will predominantly acquire

bacteria from the maternal vaginal and perianal flora. However, those delivered via Cesarean (C)-section acquire a heavy inoculum of bacteria from the maternal skin and the surrounding hospital environment. Such differences in the gut microbiota as a result of unnatural delivery have been found to persist in children until several years of life and even into young adulthood (Nagpal and Yamashiro, 2018). It has become clear that C-delivery and inadequate breastfeeding can instigate an abnormal gut microbiome composition and may also account for the rising incidences of several serious health problems in children, including asthma, allergies, celiac disease, diabetes, and obesity (Penders et al., 2006; Dominguez-Bello et al., 2010; Bäckhed et al., 2015; Bokulich et al., 2016; Tamburini et al., 2016; Chu et al., 2017). These maladies, among others, are more likely to occur in cases where an infant's gut acquires an inadequate population of health-promoting bacteria and instead is predominated by unsolicited bacteria. These gut microbes perform fundamental functions including the digestion of complex nutrients, vitamin production, stimulation of immune development, discouraging harmful bacteria, and nurturing normal maturation of the gut. Serious perturbations in one or more of these early life gut microbial functions could lead to severe health problems in the host. The infant gut is inhabited by several microbes *in utero* (Bäckhed et al., 2015; Bokulich et al., 2016; Aagaard et al., 2014; Collado et al., 2016), although the bacteria acquired during birth and the first few months of life have paramount impact on those that become permanent inhabitants in the gut.

Early-life gut microbiota in relation to the mode of delivery

In our quantitative investigation of the gut microbiota composition in Japanese infants, we found *Bacteroides fragilis* group, *Enterobacteriaceae*, *Enterococcus*, *Streptococcus*, and *Staphylococcus* to be the most prevalent dwellers, with counts ranging from 10^{5-8} cells g sample⁻¹, followed by bifidobacteria, lactobacilli, *Clostridium coccoides* group, *Clostridium leptum* subgroup, *C. perfringens*, *Atopobium* cluster, and *Prevotella* (Fig. 1A). These data demonstrated that the facultative anaerobes flourish, and hence are the first colonizers, in the nascent gut, thereby indicating a relatively aerobic intestinal environment. This also indicates that the primitive microbiota core is predominated by facultative anaerobes including *Proteobacteria*, staphylococci, streptococci, and enterococci, whereas obligate anaerobes such as Firmicutes, Bacteroidetes, and Actinobacteria start prevailing during infancy and early childhood (Fig. 1B). Compared to the meconium of vaginally born babies, the meconium of C-born babies is significantly less often colonized with the *Lactobacillus* genus (Nagpal et al., 2016). We found this difference in gut microbiota to persist up to 6 months of age.

Another study of ours performed in healthy young adults born vaginally or by C-section revealed that the C-group had significantly a lower carriage rate of the *B. fragilis* group and *Lactobacillus sakei* subgroup as compared with the vaginal-delivery group (Nagpal and Yamashiro, 2018). This suggests that some of the differences in early-life microbiota as a result of delivery mode might persist into young adulthood, even though the differences were observed in the carriage rate, but not population levels, of only two components. We did not notice any significant difference in body weight, body mass index, height, or male-female ratio by the mode of birth.

Fig. 1 Early-life gut microbiota in relation to the mode of delivery. From Nagpal R and Yamashiro Y (2018) Gut microbiota composition in healthy Japanese infants and young adults born by C-section. *Annals of Nutrition and Metabolism* 73(Suppl. 3): 4–11.

Gut microbiota in healthy toddlers to adults and the elderly

Our data indicate that gut microbiota diversity undergoes a gradual increase early in life, but reaches a plateau by 3 years of age (Fig. 2; Tsuji et al., 2012, 2018), at which time as well as at the ages of pre-school and elementary school (Wang et al., 2015), the microbial configuration and diversity become equivalent to those in adults. Further age-related quantitative changes in gut microbiota populations analysis, the predominant populations such as *C. coccoides* group, *C. leptum* subgroup, *C. perfringens*, *B. fragilis* group, and *Prevotella*, and those present at lower levels, such as *Enterobacteriaceae*, lactobacilli, and pathobionts. *Bifidobacterium* are the predominant microbiota established in most infants by 3 months after birth, particularly in those that are breastfed, and this level is maintained until the age of 3 years, with a slight decline after the introduction of solid foods. *Bifidobacterium* remains as one of the predominant microbes in adults, but in elderly people the levels are decreased. By the age of 3 years, obligate anaerobes are stabilized, but several low cell-count microbiota including *Prevotella*, *Enterobacteriaceae*, and *Enterococcus* are still in the process of transition and not yet stabilized.

The gut microbiome and immunity

The gut microbiome is a signaling hub that integrates environmental inputs, such as diet, with genetic and immune signals to affect the host's metabolism, immunity, and response to infection. These mechanisms are involved in a wide range of conditions and diseases, such as metabolic syndrome and immune-mediated diseases.

Innate immunity

The innate immune system plays an important part in shaping the community and ecology of indigenous microorganisms into configurations that can be tolerated by the host and are beneficial for its metabolic activities. This complex, bilateral interaction between the host and its microbiota has a crucial role in human health.

Intestinal epithelial cells are equipped with an extensive repertoire of innate immune receptors (Fig. 3; Thaiss et al., 2016). Intestinal epithelial cells use the recognition of microbial-cell components and metabolites to adjust their antimicrobial program and achieve metabolic homeostasis. The activation of pattern-recognition receptors (PRRs), such as Toll-like receptors (TLRs) and the NOD-like receptors (NLRs) NOD1 and NOD2, is directly coupled to the production of antimicrobial peptides (including

Fig. 2 Gut microbiota in healthy toddlers to the elderly. From Tsuji H, Matsuda K, and Nomoto K (2018) Counting the countless: Bacterial quantification by targeting rRNA molecules to explore the human gut microbiota in health and disease. *Frontiers in Microbiology* 9: 1417.

RegIII γ , RegIII β , Ang4, and Itln1) and of mucus. IL-18 plays an important part in this process through an autocrine loop (Rakoff-Nahoum et al., 2004; Slack et al., 2009). The secretion of epithelial IL-18 requires transcriptional activation through TLRs or the G-protein-coupled receptor GPR109a, and posttranscriptional cleavage through NLRP6 can also be induced by type I interferons, which functions as a sensor of viral DNA with the pre-mRNA-splicing factor ATP-dependent RNA helicase DHX15. IL-18 and IL-22 derived from immune cells also help to regulate the antimicrobial responses of epithelial cells. CCL20, which is derived from epithelial cells downstream of NOD1 signaling, is involved in the genesis of lymphoid tissue (Bouskra et al., 2008). NLRP4 promotes the expulsion of neoplastic or infected cells from the intestinal epithelium (Hu et al., 2010). PRR signaling also orchestrates the circadian clock within intestinal epithelial cells and adjusts the secretion of epithelial-derived metabolic hormones, such as glucocorticoids. Epithelial cells also respond to the levels of microbiota-modulated metabolites, such as SCFAs (acetate, butyrate, propionate), polyamines (spermine), as well as amino acids and products that are derived from them (taurine, histamine, indole). Taurine, histamine, and spermine modulate the activity of inflammasome component NLRP6. Indole modulates the levels of incretin secretion and promotes the barrier function of the epithelium through the pregnane X receptor (PXR), which helps to fortify tight junctions between cells. SCFAs serve as an energy source for epithelial cells and also support the barrier through HIF (Kelly et al., 2015). The microbial metabolite indole, through PXR, increases the secretion of glucagon-like peptide (GLP-1), an incretin with profound influence on host metabolism (Chimerel et al., 2014).

Adaptive immunity

Microbiota that establish mutualistic relationships with their hosts are able to influence a multitude of physiological functions, often through modulation of the host's immune system. Diverse species of microbes can regulate distinct branches of the adaptive immune system.

T-cell dependent IgA class-switch recombination (Fig. 4, right; Honda and Littman, 2016) takes place mostly in Peyer's patches, in which dendritic cells (DCs) that are located near the surface of the epithelium capture antigens from microbes that are transferred by M cells. DCs induce the differentiation of CD-4-expressing T cells into the T follicular helper (T_{FH}) cell subset. CD40 ligand (CD40L) and IL-21 from T_{FH} cells induce the expression of activation-induced cytidine deaminase (AID) in B cells and promote IgA class-switch recombination (Pabst, 2012; Cao et al., 2015). T-cell-independent IgA class-switch recombination (Fig. 4, left) occurs predominantly in the lamina propria and isolated lymphoid follicles (ILFs), where B-cell activating factor (BAFF; also known as TNFSF13B) and its homolog APRIL, which are derived from DCs, promote the induction of AID expression in B cells. IL-23 signals group 3 innate lymphoid cells (ILC3s) that express ROR γ to contribute to both T cell-dependent and T-cell-independent pathways

Fig. 4 Induction of IgA in mucosal tissues. From Honda K and Littman DR (2016) The microbiota in adaptive immune homeostasis and disease. *Nature* 535(7610): 75–84.

through the expression of lymphotoxin (LT)- α and LT- β , which activate DCs (Kruglov et al., 2013). The gut microbiota affect IgA class-switch recombination in both pathways. The T-cell-independent pathway produces IgA with low affinity but directed toward the microbiota. The T-cell-dependent pathway tends to be activated by bacteria that colonize the surface of the epithelium, such as segmented filamentous bacteria (SFB), *Mucispirillum*, *C. scindens*, and *Akkermansia muciniphila*. The IgA-expressing B-cell clones that this pathway induces persist for a long time and can re-enter a germinal center, where they undergo further somatic hypermutation to produce high-affinity IgA that is adapted to the changing composition of the microbiota (Cao et al., 2015; Kruglov et al., 2013).

ILC3s in adaptive immune homeostasis

Signals from the microbiota create complex interactions between epithelial cells, DCs, macrophages and ILC3s. ILC3s contribute to the differentiation of T cells and B cells. For example, ILC3s express lymphotoxin (LT)- α and LT- β , which activate DCs, thereby contributing to both T-cell dependent and T-cell-independent pathways of IgA class switching (Kruglov et al., 2013). ILC3s also facilitate the induction of T_H17 cells through the production of IL-22 and other factors. Activation of ILC3s and the induction of T_H17 cells have been observed in mice that are colonized by SFB and other bacteria, including *Citrobacter rodentium* (Atarashi et al., 2015; Sonnenberg et al., 2011; Longman et al., 2014). Activation of ILC3s by these bacteria requires the TLR-dependent activation of CX₃CR1-expressing cells (derived from monocytes) and their production of IL-23, IL-1 β , and tumor necrosis factor ligand superfamily member 15 (TNFSF15), which act through receptors on ILC3s (Longman et al., 2014). IL-22 from ILC3s then activates epithelial cells to produce serum amyloid A and other factors that are required for the induction of T_H17 cells.

ILC3s that are activated by the microbiota also promote the expansion of T_{reg} cells (Mortha et al., 2014). Gut microbiota induce the production of IL-1 β from macrophages in the lamina propria, and this cytokine acts on neighboring ILC3s to activate their production of CSF2 (Mortha et al., 2014). CSF2 then acts on CD103-expressing DCs in the colon to enhance the activity of aldehyde dehydrogenase (ALDH) and produce TGF- β and IL-10, which induce T_{reg} cells (Mortha et al., 2014).

The epithelial-innate immune system continuum in response to microbial antigens (Fig. 5)

In response to the microbiota, intestinal epithelial cells (IECs) secrete mucins and antimicrobial peptides (AMPs) that limit microbial interaction with epithelial cells. Under homeostatic, eubiotic conditions, microbe-associated molecular patterns (MAMPs) stimulate the secretion of cytokines (including TSLP, IL-33, IL-25, and TGF β) by IECs that promote the development of tolerogenic macrophages and DCs. DCs, in turn, induce the development of induced T_{reg} (iT_{reg}) cells through a TGF β and retinoic acid (RA)-dependent process. Through multiple mechanisms, including the secretion of TGF β and IL-10 by iT_{reg} cells and the secretion of IL-10 by macrophages, the anti-inflammatory balance of the intestine is maintained by inhibiting or dampening potential effector responses (Maynard et al., 2012). In addition, T_{reg} cell-derived TGF β and epithelial-derived BAFF and APRIL promote the development of IgA⁺ plasma cells to ensure an abundant supply of sIgA in the lumen, which further limits microbial interaction with the epithelium (Fig. 5A; Rakoff-Nahoum et al., 2004). In the face of pathogen invasion, mucosal injury, or dysbiosis, MAMPs stimulate the secretion of pro-inflammatory cytokines by IECs (including IL-6, IL-1, and IL-18) and intestinal DCs and macrophages (including IL-6, IL-23, and IL-12) that induce the development of the effector CD4⁺ T cells T_H1 and T_H17, the latter of which can transition to the former as a result of IL-23 or IL-12 signaling. Intestinal innate lymphoid cells, including NK-like cells, lymphoid tissue inducer cells (LTi cells), and $\gamma\delta$ IELs, respond to pro-inflammatory cytokines to upregulate IL-22, which helps to protect the epithelial barrier, and IL-17A and IL-17F, which are involved in neutrophil recruitment (Fig. 5B; Vijay-Kumar, 2008).

Microbiota-mediated immunomodulation

Microbiota-mediated effects on host immune cells and their underlying mechanisms will be instrumental in informing the rational design of microbial therapeutics (Skelly et al., 2019).

Anti-inflammatory effects of microbiota (Fig. 6)

Bifidobacterium infantis, as well as vitamin A or RA, promote DC expression of *Aldh1a2* (which encodes retinal dehydrogenase 2). *Aldh1a2*-expressing DCs can produce high levels of RA, which in conjunction with TGF β promotes the differentiation of naive T cells into forkhead box protein P3 (FOXP3)⁺ T_{reg} cells and also upregulates the expression of the gut-homing molecules α 4 β 7 integrin and CC-chemokine receptor 9 (CCR9). Polysaccharide A (PSA) from the capsule of *B. fragilis* can be transported to the intestinal lamina propria in outer membrane vesicles via an autophagy-related protein 16-like 1 (ATG16L1) and nucleotide-binding oligomerization domain-containing protein 2 (NOD2)-dependent autophagy pathway. PSA signals through TLR2 on FOXP3⁺ T_{reg} cells to induce their proliferation and the production of IL-10, thereby promoting an anti-inflammatory state. These same anti-inflammatory effects can be achieved by SCFAs derived from consortia of 46 mouse-derived or 17 human-derived *Clostridium* strains. Butyrate inhibits histone deacetylases, thus increasing transcription at the *Foxp3* promoter and a related enhancer site, and propionate signals through GPR43, among other things. Butyrate promotes M2-like macrophage polarization and thus

Fig. 5 The epithelial-innate-adaptive continuum in response to microbial antigens. From Maynard CL, Elson CO, Hatton RD, and Weaver CT (2012) Reciprocal interactions of the intestinal microbiota and immune system. *Nature* 489(7415): 231–241.

anti-inflammatory activity by upregulating arginase 1 (ARG1) expression, ultimately decreasing tumor necrosis factor (TNF) production and decreasing the expression of *Nos2*, *Il6*, and *Il12b*. Microbiota members induce CX₃CR1⁺ macrophages to restrict T helper 1 (T_H1) cell responses, promote T_{reg} cell responses, and decrease macrophage migration to the mesenteric lymph nodes (MLNs). Tryptophan is catabolized to indole by species including *Lactobacillus reuteri* and *L. murinus*. Indole derivatives signal through the aryl hydrocarbon receptor (AhR) in CD4⁺ intraepithelial lymphocytes (IELs) to downregulate T_H1-inducing POZ/Kruppel-like factor (ThPOK) expression and thus induce RUNX3 expression, thereby facilitating differentiation into CD4⁺CD8αα⁺ IELs. *Bifidobacterium bifidum* produces cell surface β-glucan/galactan (CSGG) polysaccharides, which signal through TLR2 on DCs and condition them to induce FOXP3⁺ T_{reg} cells. RORγt⁺ FOXP3⁺ T_{reg} cells are induced by several gut commensals, most potently by *Clostridium ramosum* and also by pathobionts like *Helicobacter* species under homeostatic conditions (Arpaia et al., 2013; Furusawa et al., 2013; Smith et al., 2013; Sefik et al., 2015; Ohnmacht et al., 2015; Chai et al., 2017).

Pro-inflammatory effects of microbiota (Fig. 6B)

The adhesion of SFB to the intestinal epithelium induces the transcription factor C/EBPδ, which upregulates serum amyloid A (SAA) expression. SAA induces T_H17 cells and the production of IL-17, and additionally stimulates CD11c⁺ DCs to produce IL-1β. IL-1β establishes an SAA amplification loop and induces ILC3s to produce IL-22, which signals through signal transducer and activator of transcription 3 (STAT3) on epithelial cells to further induce SAA expression. Non-adhering SFB can also activate ILC3s to produce IL-22, perhaps via IL-23 signaling. *Bifidobacterium adolescentis* and a consortium of 20 strains isolated from a patient with ulcerative

colitis can also induce T_H17 cells, potentially via epithelial adhesion. Pathobionts such as *Helicobacter* species induce antigen-specific T_H17 cells during inflammation. T_H17 cells and their related cytokines (namely, IL-17) promote a pro-inflammatory state in the gut. Commensals such as *Prevotella copri* produce succinate, which signals through GPR91 on DCs to enhance antigen-specific and TLR-driven immune responses. *Bilophila wadsworthia* reduces deconjugated taurine to sulfite, which it uses for metabolism and proliferation, triggering the induction of IFN γ -producing T_H1 cells. *Klebsiella pneumoniae* also induces IFN γ -producing T_H1 cells in a CD11b-CD103⁺ DC-dependent, TLR-dependent, and IL-18-dependent manner (Sano et al., 2015; Atarashi et al., 2015).

Immunomodulation by the microbiota (Fig. 7A–C)

Microbiota-mediated modulation of innate-like lymphocytes

Oxazoles promote indoleamine 2,3-dioxygenases (IDO) activity in epithelial cells, which in turn enhances the catabolism of tryptophan into AhR ligands such as 3-hydroxy-kynurenic acid and kynurenine. Subsequent AhR signaling promotes the presentation of lipid antigens by CD1d on the basolateral epithelial surface, in turn triggering the release of IL-13 and IFN γ by invariant natural killer T (iNKT) cells. Riboflavin derivatives can react with metabolic by-products to form pyrimidines that activate mucosal-associated invariant T (MAIT) cells by signaling through MR1. MAIT cells can enhance protection against infection with pathogens such as *Salmonella enterica* subsp. *enterica* serovar Typhimurium. *B. fragilis* produces glycosylceramides, including an α -galactosylceramide (GSL-Bf717) that potently inhibits iNKT cells in a CD1d-dependent manner, although it is unclear whether the relevant CD1d is expressed by DCs or intestinal epithelial cells (Georgel et al., 2011; Le Bourhis et al., 2013; Corbett et al., 2014).

Microbiota-mediated modulation of anticancer immunity and immune checkpoint blockade (ICB) efficacy

A consortium of 11 strains induces IFN γ ⁺CD8⁺ T cells in a CD103⁺ DC-dependent manner, thereby enhancing antimicrobial immunity against intracellular pathogens such as *Listeria monocytogenes* as well as antitumor immunity. The 11-strain consortium also produces metabolites such as mevalonate and dimethylglycine, potentially mediating the systemic induction of IFN γ ⁺CD8⁺ T cells and subsequent systemic protection. *Akkermansia muciniphila* enhances ICB efficacy by stimulating the production of IL-12 by DCs and promoting the accumulation of CCR9⁺CXCR3⁺CD4⁺ T cells in epithelial tumors and lymph nodes. *Bifidobacterium* promotes the accumulation of MHC class II^{hi} (MHCII^{hi}) DCs in melanoma tumors and enhances their capacity to stimulate T cells, resulting in an increased number of CD8⁺ T cells in tumors. Similarly, *Faecalibacterium* is associated with an increase in CD8⁺ T cells in melanoma tumors. Overall, these effects enhance ICB therapeutic efficacy (Pitt et al., 2016; Routy et al., 2018).

Microbiota-mediated modulation of host antibody response

SCFAs and saturated fatty acids produced by a subset of the intestinal microbiota activate B cells, enhancing proliferation and antibody production. However, branched-chain fatty acids, produced by species such as *Clostridium sporogenes*, inhibit these B cell processes. IgA plays a dual role in bacterial colonization; it can facilitate the clearance of certain pathogens, such as *Escherichia coli*, while enhancing mucosal colonization by commensals, such as *B. fragilis*, *Bifidobacterium animalis*, *Bacteroides thetaiotaomicron*, *Enterobacter cloacae*, and *Lactobacillus casei* (Dodd et al., 2017).

Probiotics and prebiotics in clinical use

Probiotics and prebiotics are microbiota management tools for improving host health. They target gastrointestinal effects via the gut, although direct application to other sites such as the oral cavity, vaginal tract, and skin is being explored. In this section, we describe gut-derived effects in humans.

Probiotics

Therapeutic and prophylactic effects of some probiotics for a variety of gut-related disorders might be, at least in part, mediated through modification of the microbiota and/or its function. The definition of probiotics is, as mentioned above, “live microorganisms that, when administered in adequate amounts, confer a health benefit on the host” (Sanders et al., 2019). Probiotic microorganisms act via a variety of means, including modulation of immune function, production of organic acids and antimicrobial compounds, interaction with resident microbiota, interfacing with the host, improving gut barrier integrity and enzyme formation.

Probiotic mechanisms of action (Fig. 8; Sanders et al., 2019)

Diverse mechanisms are likely to drive probiotic benefits to host health. In some cases, such as the production of antimicrobial products and cross-feeding other resident microorganisms, these mechanisms are driven directly by interactions with the resident microbiota. In other cases, such as direct interaction with immune cells, the effects might be direct via interaction with host cells. Overall, the clinical benefits delivered by probiotics could result from the combined action of several mechanisms.

Prebiotics

Prebiotics, first defined in 1995 (Gibson and Roberfroid, 1995), have been used to manipulate microorganisms in the host to improve measurable health outcomes. An update to the definition of prebiotics published in 2017 as “a substrate that is selectively utilized by host microorganisms conferring a health benefit” was made necessary by the need to clarify what did and did not constitute a prebiotic substance in the face of scientific advances (Gibson et al., 2017). Prebiotic effects include defense against pathogens, immune modulation, mineral absorption, improved bowel function, metabolic effects, and satiety.

Identified mechanisms of action of prebiotics (Fig. 9)

The premise is that prebiotics enter the gut and are selectively utilized. This step increases bacterial growth and functionality of specific genera or species. As a result of either or both of these effects, health benefits can accrue. Fecal bulking and improved bowel habits occur due to microbial growth. Immune regulation can be influenced by increased biomass and cell wall components of the bacteria. Metabolic products include organic acids, which lower intestinal pH and have concomitant effects upon microbial pathogens and mineral absorption. Metabolic products can also influence epithelial integrity and hormonal regulation. Bacteria that respond to prebiotic intake can influence the microbiota composition through elaboration of antimicrobial agents (for example, peptides) and competitive interactions, possibly reducing infections and bacteria containing lipopolysaccharide.

Clinical use

Many clinical gastrointestinal indications could benefit from probiotic and prebiotic interventions. For clinical use, it is required to have a better understanding of the characteristics of the host (including diet, baseline microbiota, medications, and disease) that improve in response to probiotics or prebiotics. Clinicians also need clarification about probiotic and prebiotic products: are they safe, who will benefit (how and to what extent), and can the product labels be trusted?

Fig. 9 Identified mechanisms of action of prebiotics. From Sanders ME, Merenstein DJ, Reid G, Gibson GR, and Rastall RA (2019) Probiotics and prebiotics in intestinal health and disease: from biology to the clinic. *Nature Reviews Gastroenterology & Hepatology* 16(10): 605–616.

Commercial strains of probiotics and their sources

Probiotic products consist of different enzymes, vitamins, capsules, or tablets, and some fermented foods contain microorganisms that have beneficial effects on the health of the host. They can contain one or several species of probiotic bacteria. Most probiotic products destined for human consumption are in the form of fermented milk or given in powder or tablet forms. The probiotic bacteria generally belong to the genera *Lactobacillus* and *Bifidobacterium*. However, there are other bacteria, some of which are listed in Table 1 (Nagpal et al., 2014).

Effects of probiotics on health

There are many clinical indications for the use of certain probiotic strains supported by robust evidence. In pediatric and/or adult populations, the clinical conditions shown in Table 2 have been suggested as indications for the use of probiotics.

Prebiotics in clinical use

Generally, the strength of evidence for prebiotic interventions lags behind that for probiotics. Perhaps the strongest support for prebiotic use comes from prebiotic infant formulae. Such products are now routinely supplemented with mixtures of galactooligosaccharides and fructans (Arslanoglu et al., 2007, 2008), and this blend of prebiotics in a 9:1 ratio has been shown to reduce respiratory tract infections to levels found in breastfed infants (Jippes et al., 2013; Boehm et al., 2004; Shahramian et al., 2018).

Much of the research focus on prebiotics has been in the realm of functional foods (those that improve wellbeing through benefits beyond their nutrient content). The replacement of glycemic carbohydrates in food products with non-glycemic carbohydrates to reduce post-prandial glycemic responses has already received a positive European Food Safety Authority opinion (EFSA Panel on Dietetic Products, Nutrition and Allergies (NDA), 2014).

Prebiotic foods designed to increase satiety and reduce energy intake are a promising approach to augmenting compliance with weight-loss diets. Oligofructose-enriched inulin in overweight children has been shown to increase satiety and reduce energy intake.

Table 1 Some commercial probiotic strains.

Strain	Source
<i>L. acidophilus</i> NCFM	Rhodia, Inc. (Madison, Wisconsin, United States)
<i>Lactobacillus brevis</i> KB290	Kagome Co., Ltd. (Tochigi, Japan)
<i>L. acidophilus</i> DDS-1	Nebraska Cultures, Inc. (Lincoln, NE, United States)
<i>L. acidophilus</i> SBT-2062	Snow Brand Milk Products Co., Ltd. (Tokyo, Japan)
<i>B. longum</i> SBT-2928	
<i>L. acidophilus</i> R0011	Institut Rosell (Montreal, Canada)
<i>L. rhamnosus</i> R0052	
<i>L. paracasei</i> CRL431	Chr. Hansen (Horsholm, Denmark)
<i>B. lactis</i> Bb-12	
<i>L. casei</i> Shirota	Yakult Honsha Co., Ltd. (Tokyo, Japan)
<i>B. breve</i> strain Yakult	
<i>L. casei</i> DN014001 (Immunitas)	Danone Le Plessis-Robinson (Paris, France)
<i>L. fermentum</i> RC-14	Urex Biotech Inc. (London, Ontario, Canada)
<i>L. rhamnosus</i> GR-1	
<i>Streptococcus thermophilus</i> MN-ZLW-002	Inner Mongolia Mengnuu Dairy Industry Co., Ltd. (Hohhot, China)
<i>L. johnsonii</i> La1 (same as Lj1)	Nestlé (Lausanne, Switzerland)
<i>L. plantarum</i> 299V	Probi AB (Lund, Sweden)
<i>L. rhamnosus</i> 271	
<i>L. reuteri</i> SD2112 (same as MM2)	BioGaia (Raleigh, North California, United States)
<i>L. rhamnosus</i> GG	Valio Dairy (Helsinki, Finland)
<i>L. rhamnosus</i> LB21	Essum AB (Umeå, Sweden)
<i>L. salivarius</i> UCC118	University College (Cork, Ireland)
<i>B. longum</i> BB536	Morinaga Milk Industry Co., Ltd. (Kanagawa, Japan)
<i>B. lactis</i> HN019 (DR10)	New Zealand Dairy Board
<i>L. acidophilus</i> LB	Lacteol Laboratory (Houdan, France)
<i>L. paracasei</i> F19	Aria Dairy (Stockholm, Sweden)
<i>L. crispatus</i> CTV05	Gynelogix, Boulder, Colo.
<i>L. casei</i> DN114	Danone (Paris, France)
<i>S. boulardii</i>	Biocodex Inc. (Seattle, Washington, United States)
<i>L. delbrueckii</i> subsp. <i>bulgaricus</i> 2038	Meiji Milk Products (Tokyo, Japan)

^cNo official recommendations have been made for the use of probiotics in adults.

Expectations for the future

The gut microbiota might be central to the cause of many disorders, and its modulation could hold the key to effective new therapies. So, what are the roles of probiotics and prebiotics? In a general sense, both interventions serve to increase the community of beneficial microorganisms and the products of their growth and metabolism.

The field is poised for conceptual advances. Target microorganisms will expand beyond the typical *Bifidobacterium* spp. and *Lactobacillus* spp. to include other genera and perhaps more yeast species. These microorganisms might be new probiotic candidates or further targets for prebiotic utilization. To obtain robust evidence that gut microbiome alterations can reduce disease incidence or mitigate disease, more well-designed randomized controlled trials are needed. Ultimately, the application of probiotic and prebiotic regimens has the potential to improve human health and contribute greatly to how patients are managed and/or disease risk is reduced.

Introduction

A biofilm is an important form of microbial ecology, discovered in 1684. This microbial form of life promotes protection for the microbial community, making them resistant to the hostile environment, conventional disinfection methods, physical washing, and resistance to antimicrobial treatment (Hancock and Brinkman, 2002; Vasudevan, 2014). Bacterial biofilms are formed by microbial cells adhered to abiotic or biotic surfaces encased in a complex self-produced matrix composed of extracellular polymeric substances, including exopolysaccharides, extracellular DNAs (eDNA) and proteins (Rabin et al., 2015; Pakharukova et al., 2018).

Biofilms can be beneficial when associated with plants, animal and human microbiomes and can be crucial for industrial processes, such as water treatment. However, biofilms often cause significant problems for human health, as they are the basis of chronic infections and for industry, since they arise on the surfaces of tubes and obstruct filtration devices (Yan and Bassler, 2019; Sharma et al., 2019).

The biofilm formation process comprises a series of sequential phases involving genetic, environmental factors and complex mechanisms guided by chemical, physical and biological processes (Chatterjee and Otto, 2013; Coughlan et al., 2016; Tan et al., 2020). Bacterial biofilms have about 90% extracellular matrix and 10% microorganisms in their composition (Satpathy et al., 2016; Sun et al., 2020).

The elimination of biofilm becomes relevant, as it is estimated that between 65% and 80% of infections are associated with the production of this virulence factor (Eze et al., 2018; Williams et al., 2020). Besides, biofilms are commonly associated with healthcare-related infections, and they are a mattering factor in the development of antimicrobial resistance (Bodelón et al., 2016; Piperaki et al., 2017; Flament-Simon et al., 2019).

Due to therapeutic failure associated with biofilm production, microbial infections have been consolidated as one of the leading causes of death worldwide, causing hospitalization, patient suffering and reduced quality of life (Wu et al., 2015; Ciofu et al., 2015; Ramasamy and Lee, 2016). The treatment of biofilm-producing strains infections is costly and challenging due to the limited spectrum of antimicrobials effectively eliminating these bacteria (Bassetti et al., 2019; de Oliveira Júnior and Franco, 2020).

The lack of antimicrobials to treat patients with biofilm-producing microorganisms concerns health professionals, the scientific community, and the world population. To overcome this problem, the scientific community have been searching for new molecules with potential antibiofilm action in parallel to the development of new therapeutic strategies (Tran et al., 2020; Zhang et al., 2020; Pinto et al., 2020). Thus, this book chapter aimed to gather the most relevant studies applying nanocarriers and external physical stimuli to treat bacterial biofilms.

Biofilms

The biofilm was first discovered in 1684 from the observation of bacterial clusters in dental plaques. Since then, biofilms have been one of the most successful forms of life present in human and animal infections, food, and water (Ciofu et al., 2017; van Wolferen et al., 2018; Olivares et al., 2020; Silva et al., 2020). Biofilm can also be defined as a sessile agglomerate of single microbial species or

a combination of different microbial cell types immersed in an extracellular polymeric matrix. It is composed of exopolysaccharides (EPS), proteins, lipids and DNA adhered to a biotic or an abiotic surface (Desmond et al., 2018). Besides, it presents interstitial spaces, such as macro and micro-colonies, that facilitate the diffusion of nutrients and gases (Singh et al., 2017).

The biofilm acts by limiting the diffusion of antimicrobials, promoting colonization with greater structural stability and greater longevity of microorganisms in the target site. It also acts as a physical barrier, protecting against environmental stresses such as ultraviolet (UV) radiation, pH, chemical exposure, osmotic pressure variations, phagocytosis, and desiccation (Olivares et al., 2020).

Biofilms are considered a natural process, sometimes beneficial, such as a natural element of microbiomes, and essential for the industry in the effective treatment of wastewater. However, the ability that certain microorganisms have to form biofilms represents one of the possible virulence mechanisms responsible for the failure of antimicrobial therapy and a bacterial survival strategy (Yan and Bassler, 2019).

Biofilm formation is an essential factor in the virulence of microorganisms related to chronic infections and in the emerging scenario of bacterial resistance, being present in 65–80% of recurrent bacterial infections (Venkatesan et al., 2015). The problem of antimicrobial resistance is growing, and the prospect for developing new effective antimicrobials in the future is still uncertain (Antoñanzas and Goossens, 2019).

Formation of biofilms

The synthesis of biofilm can be established in a few hours. It consists of a highly regulated and dynamic mechanism regarding the transition process of microorganisms in planktonic life to the biofilm's sessile way of life (Magana et al., 2018). The biofilm regulates its architecture due to responses from the internal and external environment. Its density varies according to the type of microorganism and the conditions of the environment in which it finds itself (Germec et al., 2020).

During the transitional process of the planktonic state to the sessile, bacteria continually change their phenotype. They can become highly resistant to antimicrobials and components of the host's innate and adaptive immune system, contributing significantly to the failure of antimicrobial therapy. This protection provided by the biofilm extends to Gram-positive and Gram-negative bacteria, mobile and non-mobile, aerobic, anaerobic, protozoa, archaea, algae, filamentous fungi and yeast (Costa-Orlandi et al., 2017; Raghupathi et al., 2018; Muhammad et al., 2020).

The biofilm formation, in general, can be presented through five stages: a reversible connection of cells to a surface, followed by irreversible adhesion, maturation I and II and finally, the dispersion of the biofilm (Fig. 1) (Roy et al., 2018).

The structuring, maturation and dissemination of biofilm is a highly controlled process. The main regulators responsible for this phenotype is the cell-to-cell signaling mechanism known as *Quorum Sensing* (QS) (Verderosa et al., 2019).

QS is a cell-to-cell communication mechanism, regulator cell density-dependent gene expression, found in Gram-negative and Gram-positive bacteria (Schilcher and Horswill, 2020). Regulation by the QS maintains the ideal biofilm size, preventing the cell density of the biofilm from reaching an unsustainable level, activating specific genes that lead to the expression of virulence factors, such as enzymes and/or toxins, ensuring their adaptation to the most diverse environmental conditions (Dickschat, 2010; Verderosa et al., 2019).

Antibiotics resistance and clinical importance of biofilms

Antimicrobial resistance has become a significant public health problem and, consequently, a mattering threat to human health. The annual mortality rate of infections caused by multidrug-resistant (MDR) microorganisms in 2050 is predicted to increase to 10 million, generating an estimated economic impact of U\$ 100 trillion (Crabbé et al., 2019). Bacterial resistance to antibiotics is the bacterium's ability to survive at concentrations of antibiotics capable of inhibiting/killing other ones of the same species (Alós, 2015). The resistance reflects the increase of the minimum inhibitory concentration (MIC) (Brauner et al., 2016).

Fig. 1 Schematic illustration of the biofilm formation. Created by the authors.

Biofilm promotes increased cell tolerance, as sessile bacteria alone tend to be about 500–5000 times more tolerant than their planktonic state (Vergidis and Patel, 2012; Khatoon et al., 2018). Tolerance begins when bacteria aggregate in high density, which generates a gradient of nutrients, restricting the antimicrobial penetration into the biofilm (Fux et al., 2003). In a biofilm, it was observed that the release of bacteriophage-mediated eDNA favors the emergence of tolerant colonies (Hall and Mah, 2017). Thus, the tolerance and multidrug resistance observed in biofilm-forming bacteria have represented a challenge for current therapies (Ciofu et al., 2017).

Biofilm represents one of the virulence factors associated with the pathogenesis of several bacterial pathogens. The variety of clinical conditions attributed to or associated with bacterial biofilms is large. They range from the most common such as tooth decay to chronic conditions, such as cystic fibrosis (Verderosa et al., 2019). They are particularly problematic when associated with medical devices, fomites, and wound infection (Hughes and Webber, 2017).

About 40–80% of bacterial cells can live in biofilms, and according to the Centers for Disease Control and Prevention (CDC), about 65% of Healthcare-Associated Infections (HAIs) are due to the production of biofilms (Percival, 2017; Flemming and Wuertz, 2019). Most HAIs are often associated with prolonged treatments, higher rates of morbidity and mortality and therapeutic failures due to the resistance guaranteed by the biofilm, which represents a considerable economic burden (Del Pozo, 2018).

Thus, its presence has severe implications for choosing the most effective therapeutic option for the treatment of the patient and management of the microorganism, preventing its spread in different nosocomial environments and/or in the community (Percival, 2017). Finally, the treatment of bacterial biofilms still represents a challenge due to the absence of efficacious drugs with antibiofilm activity, both for preventing and treating infections caused by producing microorganisms (Ciofu et al., 2015). Eradication of biofilms is problematic because high doses of commercial antimicrobials are required, increasing the risk of systemic toxicity, leading to adverse effects detrimental to the patient's health (Hurlow et al., 2015; Yan and Bassler, 2019).

Treatment of bacterial biofilms

The treatment of biofilms can follow two approaches, one through the inhibition of biofilm formation and the other related to the eradication or treatment of the formed biofilm (Khatoon et al., 2018; Banerjee et al., 2019). The prevention strategy for biofilm formation is based on blocking bacterial growth using antimicrobial agents. Blockade can occur through inhibition of bacterial adhesion or due to disruption of cellular communication (Kostakioti et al., 2013; Lebeaux et al., 2014; Manner et al., 2017; Paluch et al., 2020).

To assess the activity of antibiotics against biofilms, these drugs are evaluated for minimum inhibitory biofilm concentration (MBIC) and minimum biofilm eradication concentration (MBEC) (Cruz et al., 2018; Thieme et al., 2019). MBIC is determined as the lowest concentration of an antimicrobial agent needed to inhibit biofilm formation (Perumal and Mahmud, 2013). Molecules or substances that act by inhibiting biofilm play an essential role in preventing biofilm formation and eradication are of great use in the use of hospital medical material surfaces (Roy et al., 2018; Abebe, 2020). MBEC is defined as the lowest concentration of an antimicrobial agent that is necessary to eradicate the formed biofilm (Venkatesan et al., 2015; Thieme et al., 2019).

As for the biofilm eradication mechanisms, the strategies are based on the replacement of contaminated biomedical devices or on the use of antibiotics capable of dissolving the biofilm through enzymes and other molecules that can disintegrate the matrix of EPS (Fig. 2) (Roy et al., 2018; Verderosa et al., 2019; Munir et al., 2020). Another strategy is the association of antimicrobial agents, one that manages to perforate the biofilm structure and the other that penetrates the biofilm and acts on microorganisms (Fig. 2) (Gebreyohannes et al., 2019; Munir et al., 2020).

The biofilm matrix contains protein material, extracellular DNA and polysaccharides, making it more susceptible to degradation by exogenous enzymes such as proteinase K, trypsin and DNase I. The use of these enzymes associated with antimicrobial agents can be an alternative for eradicating biofilms (Fagerlund et al., 2016; Nahar et al., 2018; Jiang et al., 2020; Karygianni et al., 2020).

To identify whether the antibiotic presents antibiofilm activity, the MBIC or MBEC are assessed. The MBIC and MBEC values are important because in vitro studies comparing MIC with MBIC or MBEC assays show that there are differences in the sensitivity patterns of antibiotics. Biofilms are more resistant, requiring a higher concentration of drugs to prevent or eradicate the biofilm (Mulla et al., 2016; Shimizu and Harada, 2017; Madheswaran et al., 2018; Rudilla et al., 2018; Thieme et al., 2019).

The treatment of biofilm infections is, without doubt, a challenging approach. Studies describe that the treatment of newly formed biofilms is likely to be eliminated using only antibiotics compared to already well-developed biofilms. This information reinforces the importance of diagnosing early infection to achieve an efficient treatment (Taraszkievicz et al., 2013; Koo et al., 2017; Roy et al., 2018; Gebreyohannes et al., 2019).

Fig. 2 Illustration of the antibiofilm agents' action. (A) EPS degradation; (B) Cell signaling; (C) Biofilm degradation; (D) Antibiofilm target. Created by the authors.

The treatment of bacterial biofilms could be divided into three main strategies. The first one is based on surgical debridement of devitalized tissues, followed by continuous irrigation of a biocide and/or antiseptic, and then using antibiotics by endovenous route for a systemic action (Attinger and Wolcott, 2012; Edmiston et al., 2016). Another strategy applied to infections caused by the presence of biofilm in a medical device is the removal and/or replacement of the device followed by the selection and use of systemic antimicrobials (Wu et al., 2015; Høiby et al., 2015; Khatoon et al., 2018).

Nanotechnology

Nanotechnology has gained significant importance due to its applications in preventing, diagnosing, and treating various diseases. This technology provides several combinations of materials or devices with drugs and biomolecules, bringing benefits such as drug-controlled release, which, in turn, increase drug circulation time and the half-life, decreased toxicity and could target the encapsulated drug to a specific site. Nanomaterials can be developed to potentiate the activity of antibiotics with minor side effects and can potentiate the activity of antibiotics (Ramos et al., 2018; Naskar and Kim, 2019).

As illustrated in Fig. 3, the encapsulation of antibiotics and other active substances can occur through different nanocarriers, such as liposomes, solid lipid nanoparticles, polymeric nanoparticles, inorganic nanoparticles, among others (Pircalabioru and Chifiriuc, 2020).

Drug-resistant bacteria and biofilm-associated infections are challenging to treat due to the inherent resistance to antimicrobial agents. Encapsulation of these agents into nanocarriers then becomes a strategy used to increase the efficacy of these drugs and turn biofilm eradication possible. The nanocarriers can provide the entry of the drug into the biofilm, improving the efficacy of the treatment while reducing toxic levels (Yeh et al., 2020).

Nanomaterials in the treatment of biofilm-driven infections can be subdivided into three groups. The first group includes nanomaterials that possess intrinsic biofilm eradication properties. The second group comprises those that serve as carriers of molecules with antimicrobial properties. Finally, the third covers responsive nanomaterials, usually metal nanoparticles or nanocarriers, that possess the ability to disrupt biofilm physics (Tran et al., 2020).

A range of nanomaterials can be used against biofilms because of their intrinsic antimicrobial properties, due to the composition of nanomaterials or because they can encapsulate natural compounds or synthetic drugs. The interaction of nanocarriers with bacterial cells can cause cell membrane damage, oxidative stress mechanisms, inactivation of enzymes primordial to metabolism, and gene alterations preventing biofilm formation. In the preformed biofilm, nanoformulations can penetrate or release substances on the biofilm surface, facilitating the penetration of the drug, to preventing cell signaling and disassemble the extracellular polymeric matrix (Fig. 4) (Rukavina and Vanić, 2016; Mihai et al., 2018; Chaudhary et al., 2020).

Liposomes

Liposomes are lipid nanocarriers used to deliver active molecules with antimicrobial potential. In this sense, recent studies demonstrate the potential for delivering molecules and drugs with potential antibiofilm (Table 1) (Rukavina and Vanić, 2016).

Alhariri et al. (2017) evaluated the antibiofilm activity of gentamicin loaded in liposomes (NELG-1 and NELG-2) against *P. aeruginosa* BAA1744 and *Klebsiella oxytoca* 700,324. The sizes of NELG-1 and of NELG-2 were 691.3 ± 3.3 nm and 806.6 ± 3.4 nm, and the zeta potential was 25.3 ± 2.5 mV and 31.7 ± 1.7 mV, respectively. The percentage of gentamicin loaded in these formulations was $37.2 \pm 0.46\%$ for NELG-1 and $43.6 \pm 0.65\%$ for NELG-2. It was observed that liposomes at a concentration of $1/2 \times \text{MIC}$ ($0.125 \mu\text{g mL}^{-1}$) showed an inhibitory effect on the biofilm of *P. aeruginosa* and *K. oxytoca* for NELG-1 and NELG-2. In comparison, eradication of the structured biofilm of *P. aeruginosa* and *K. oxytoca* was achieved at a concentration of $16 \times \text{MIC}$ ($4 \mu\text{g mL}^{-1}$) for NELG-1 and NELG-2.

Hou et al. (2017) prepared liposomes containing gentamicin associated with lysozyme. Lysozyme-associated liposomal gentamicin (LLG) was prepared by vesicle extrusion technique, and the average particle size and zeta potential were 104 nm and 17.5 mV, respectively. This treatment significantly reduced the biofilm formation (80–90%) and preformed biofilm (85%–95%) of *Staphylococcus aureus* ATCC 29213 and *Pseudomonas aeruginosa* PA01 biofilm. Quantification of biofilm biomass and cell viability demonstrated that the formulation had a more pronounced effect than gentamicin or lysozyme alone.

Li et al. (2019) prepared cationic liposomes encapsulating cefquinome sulfate (CSCLs) and evaluated their antibiofilm activity against *Staphylococcus aureus* ATCC 25923. CSCLs were prepared by the solid dispersion method combined with effervescent hydration. The average particle size of the CSCLs was 201.5 nm, the zeta potential of +65.29 mV, and the encapsulation efficiency was 63.21%. Eradication of preformed biofilm was observed, reaching 81.30% in 24 h at a concentration of $2.5 \times \text{MIC}$ ($1.2 \mu\text{g mL}^{-1}$). Scriboni et al. (2019) formulated fusogenic liposomes containing vancomycin against *Staphylococcus aureus* biofilm-producer ATCC 29213. Treatment using this formulation showed an inhibitory effect at $2 \times \text{MIC}$ ($3.13 \mu\text{g mL}^{-1}$).

Ghodake et al. (2020) developed liposomes containing cefoperazone sodium to eliminate *P. aeruginosa* biofilm in cystic fibrosis infection. The liposomes were formulated using the lipid thin film hydration method and had a particle size of 410.85 ± 26 nm, PDI of 0.4, a zeta potential of -18.3 mV and encapsulation efficiency of $68.90 \pm 3\%$. It was observed that there was 50% and 87% inhibition of biofilm formation at concentrations of $1 \mu\text{g mL}^{-1}$ and $250 \mu\text{g mL}^{-1}$, respectively. It was also observed that there was the eradication of the preformed biofilm in 50% and 91% at the same concentrations, respectively.

Bazrgari et al. (2020) evaluated the antibiofilm activity of nanoliposomal formulations of rifampicin and *N*-acetyl cysteine (NAC) against *Staphylococcus epidermidis* (DSMZ 3270) biofilm. The liposomal formulations were prepared by the solvent evaporation method, and the liposomes containing rifampicin presented particle size of 125.23 ± 6.40 nm, PDI of 0.124 ± 0.001 , the zeta potential of $+30.76 \pm 1.31$ mV and encapsulation efficiency $90 \pm 5\%$, while the liposomes containing rifampicin and NAC presented a particle size of 180 ± 2.32 nm, PDI of 0.200 ± 0.02 , the zeta potential of $+54.33 \pm 2.96$ mV and encapsulation efficiency $80 \pm 3\%$ for rifampicin and $18 \pm 2\%$ for NAC. The eradication of bacterial biofilm and the inhibition of biofilm formation were evaluated based on the optical density ratio. The antibiofilm activity of most of the formulations was concentration-dependent and time-dependent.

Aiello et al. (2021) prepared liposomes composed of DOPC and cholesterol (Chol) with mannose residues (MAN1), galactose residues (GLT1) or glucose residues (GL4) encapsulating resveratrol and evaluated their antibiofilm activity against biofilm of MRSA clinical isolates. The liposomes developed exhibit an average particle size of 95 nm, PDI of 0.2, zeta potential around 23 mV and encapsulation efficiency above 90%. It has been observed that the mannosylated and galactosylated liposomes can eradicate the preformed MRSA biofilm at concentrations ranging from 0.019 mM to 1.2 mM.

Shirin et al. (2021) evaluated the potential of meropenem encapsulated in a niosome against MRSA strains. The formulation presented an average particle size of 51.3 ± 5.84 nm, PDI 0.131, the zeta potential of -65.29 ± 2.6 mV, encapsulation efficiency of $84.86 \pm 3.14\%$ and presented MBIC of $0.125 \mu\text{g mL}^{-1}$ for MRSA ATCC 33592 and MBICs between $0.062 \mu\text{g mL}^{-1}$ and $0.25 \mu\text{g mL}^{-1}$ for six MRSA clinical isolates from hospitals in Tehran, Islamic Republic of Iran. Studies show that liposomes are promising in administering antibiotics in the therapy of biofilm-related bacterial infections due to their ability to decrease MICs and the MBICs and penetrate biofilms enabling the delivery of the active molecule compared to conventional therapy (Rukavina and Vanić, 2016).

Polymeric nanoparticles

Polymeric nanoparticles are nanocarriers discovered in the 1970s that have become promising in drug delivery, including drugs with antibacterial potential. Research is carried out encapsulating active molecules with potential antibiofilm (Table 2) (Chaudhary et al., 2020).

The study conducted by Cui et al. (2018) evaluated the antibiofilm activity of chitosan nanoparticles loaded with clove oil (CO@CNPs) against biofilms of *Escherichia coli* O157:H7. CO@CNPs were prepared following the ionic cross-linking method. The average particle size of CO@CNPs was between 154.9 ± 3.0 nm to 236.3 ± 2.6 nm. The CO@CNPs showed PDI ranged between 0.266 ± 0.023 and 0.297 ± 0.032 . The zeta potential of all CO@CNPs prepared ranged from 30.9 ± 2.2 mV to 44.3 ± 2.3 mV, and the encapsulation efficiency was $39.6 \pm 0.8\%$. The antibiofilm activity of CO@CNPs was observed with a 99.98% reduction in *E. coli* O157:H7 biofilm after 8 h of treatment.

Subhaswaraj et al. (2018) evaluated the antibiofilm potential of chitosan nanoparticles encapsulating cinnamaldehyde (CANPs) against *Pseudomonas aeruginosa* PAO1. CANPs were synthesized by ionic gelation method and presented average diameter size, PDI and encapsulation efficiency of 208.12 nm, 0.277 and $65.04 \pm 2.14\%$, respectively. The inhibition of biofilm formation by CANPs was $63.59 \pm 2.5\%$ and $84.06 \pm 4.09\%$ at subinhibitory concentrations of $250 \mu\text{g mL}^{-1}$ and $500 \mu\text{g mL}^{-1}$, respectively.

Tan et al. (2018) developed chitosan nanoparticles containing oxacillin (OXA) and deoxyribonuclease I (CSNP-DNase-Oxa), targeting biofilm cells and biofilm matrix of *Staphylococcus aureus* ATCC 6538. Biofilm reduction was achieved with all concentrations tested ($1, 0.5, 0.25, 0.125$ and $0.0625 \mu\text{g mL}^{-1}$). Both the free and encapsulated OXA showed promising results on biofilm inhibition. The lowest concentration ($0.0625 \mu\text{g mL}^{-1}$) inhibited about 60% of biofilm formation, and almost no biofilm formation was observed at concentrations higher than $0.5 \mu\text{g mL}^{-1}$. Repeated treatment with CSNP-DNase-OXA for 2 days resulted in a 98.4% reduction of *Staphylococcus aureus* biofilm.

Ma et al. (2020) encapsulated curcumin in chitosan nanoparticles (CSNP-Cur) and evaluated their antibiofilm activity against *S. aureus* ATCC 6538. The average diameter of CSNP-Cur was 134.37 ± 1.99 nm, the zeta potential of

$+18.10 \pm 0.82 \text{ mV}$ and encapsulation efficiency of $91.95 \pm 0.63\%$. At concentrations up to $400 \text{ }\mu\text{g mL}^{-1}$, CSNP-Cur reduced the preformed biofilm by 88.48%. In comparison, Siddhardha et al. (2020) encapsulated chrysin in chitosan nanoparticles (CCNPs) and tested the antibiofilm activity against *S. aureus* MCC 2408. The average diameter of the synthesized CCNPs was 355 nm, PDI of 0.487 and encapsulation efficiency of $80.86 \pm 0.30\%$. The biofilms were inhibited by 66.59% at a concentration of $768 \text{ }\mu\text{g mL}^{-1}$. The treatment of the preformed biofilm with CCNPs also reduced the biofilm mass by 43.50% at the same concentration.

Scutera et al. (2021) evaluated the antibiofilm effect of human albumin nanoparticles coated with chitosan containing colistin (Col/haNPs) against antibiotic-resistant *A. baumannii* strains. Col/haNPs were prepared by the double-emulsion method and showed average size of $176.1 \pm 0.9 \text{ nm}$, PDI of 0.12, zeta potential of $+28.05 \pm 2.1 \text{ mV}$ and encapsulation efficiency of 98.65%. Col/haNPs inhibited biofilm formation between 50% and 95% at concentrations of MIC, $1/2 \times \text{MIC}$ and $1/4 \times \text{MIC}$ for *A. baumannii* Col R1 and S strains within 24 h. Already, Gheffar et al. (2021) developed nanoparticles of Poly (lactic-co-glycolic acid) (PLGA) containing ciprofloxacin and evaluated the potential antibiofilm against *S. aureus* ATCC 29213. The particles were obtained by nanoprecipitation and showed an average size of $81 \pm 7 \text{ nm}$, the zeta potential of $-45 \pm 10 \text{ mV}$ and encapsulation efficiency of $3.6 \pm 1.3\%$. The MBECs were $25 \text{ }\mu\text{g mL}^{-1}$ and $12.5 \text{ }\mu\text{g mL}^{-1}$ after 24 h and 48 h of incubation, respectively.

Da Costa et al. (2021) developed nanoparticles of poly-lactic acid (PLA) that were surface functionalized by poly-L-lysine encapsulating rifampicin (NP-RIF-PLL) and evaluated their potential antibiofilm against *S. aureus* SH1000. NP-RIF-PLL was synthesized by a nanoprecipitation process and presented a particle size of $162 \pm 2 \text{ nm}$, PDI of 0.06 ± 0.02 , the zeta potential of $+40 \pm 2 \text{ mV}$ and encapsulation efficiency of $83.7 \pm 0.4\%$. Partial degradation of the biofilm was observed since at least 70% of the biofilms remained adhered after 24 h of treatment with NP-RIF-PLL. The authors highlight the ability of the loaded nanoparticles to interact with bacterial cells, migrate and accumulate in biofilms, and the effect of this passive targeting and accumulation on the efficacy of antibiotic treatment in planktonic cells and biofilms. Thus, the studies about polymeric nanoparticles demonstrate that the properties of the nanoparticles allow the delivery of drugs, making it possible to increase the effectiveness of therapy compared to conventional methods to combat biofilms produced by different infectious pathogens that cause disease in the human body (Chaudhary et al., 2020).

Inorganic nanoparticles

Inorganic nanoparticles appear as a potentially important option in antibacterial and antibiofilm therapy (Table 3) (Mihai et al., 2018).

In that regard, Habash et al. (2017) determined the effects of silver nanoparticles (AgNP) on the biofilm eradication of *Pseudomonas aeruginosa* PA01. The MBEC for AgNP of 10, 20, 40 and 60 nm were 1.25–5 $\mu\text{g mL}^{-1}$, 1.25–5 $\mu\text{g mL}^{-1}$, 2.5–10 $\mu\text{g mL}^{-1}$ and 5–10 $\mu\text{g mL}^{-1}$, respectively.

Yu et al. (2018) evaluated the antibiofilm potential of silver nanoparticle-decorated quercetin nanoparticles (QA NPs) against a multidrug-resistant *Escherichia coli* ECDCM1 strain. At a QA NPs concentration of 20 $\mu\text{g mL}^{-1}$, biofilm formation was inhibited about 90%. While Alavi et al. (2019) synthesized metallic nanoparticles (MNPs) of Ag and Cu and oxide metal nanoparticles (MONPs) of TiO₂, ZnO and Fe₃O₄ green through the aqueous lichen extract of *Protaparmeliopsis muralis* and evaluated the inhibition of biofilms of *S. aureus* ATCC 43300, *E. coli* ATCC 25922 and *P. aeruginosa* ATCC 27853. The antibiofilm effect of Ag, Cu and ZnO NPs was observed at a concentration of 100 $\mu\text{g mL}^{-1}$. In *E. coli* biofilms, Ag, Cu and ZnO NPs inhibited formation by 80% and 85%. For *S. aureus*, there was a reduction between 70% and 80%, and for *P. aeruginosa*, inhibition was observed around 80% and 90%.

Farooq et al. (2019) developed silver nanoparticles conjugated to rifampicin (Rif-Ag) with potential antibiofilm against MRSA ATCC 43300 and *K. pneumoniae* ATCC 13882. Rif-Ag was synthesized by the Turkevich method and presented an average particle size between 15 nm and 18 nm. MBIC was 1 $\mu\text{g mL}^{-1}$ for *K. pneumoniae* and 0.0003 $\mu\text{g mL}^{-1}$ for MRSA, while at the concentration of 1 $\mu\text{g mL}^{-1}$, the *K. pneumoniae* and MRSA biofilms were eradicated in $40.25 \pm 0.9\%$ and 69.21 ± 1.4 , respectively.

Muthuchamy et al. (2020) investigated the antibiofilm action of graphene/chitosan nanoparticles (GR/CS NCs) against *P. aeruginosa* MTCC 2453 and *K. pneumoniae* MTCC 3384 biofilm producers. MBIC was determined at a concentration of

40 $\mu\text{g mL}^{-1}$ for GR/CS NC against both strains. Already, Banerjee et al. (2020) developed zinc oxide nanoparticles doped with pancreatin (ZnONPs-PK) and evaluated the inhibition of biofilm formed by MRSA strains. The nanoparticles showed an average diameter of 5 nm, PDI of 0.641, and the percentage of protein adsorbed on nanoparticles surface was $0.47 \pm 0.4\%$. The inhibition of biofilm formation at MIC concentration ($75 \mu\text{g mL}^{-1}$) and $1/2 \times \text{MIC}$ ($37.5 \mu\text{g mL}^{-1}$) were 84% and 66%, respectively. Regards the eradication of biofilm, ZnONPs-PK inhibit 66% and 47% at MIC and $1/2 \times \text{MIC}$ concentrations, respectively.

Pauzi et al. (2021) evaluated the antibiofilm properties of ZnO nanoparticles with gum arabic against *S. aureus* and *E. coli* strains. The formulations had a particle size of 180 nm and zeta potential of 10.8 mV. At concentrations equal to or above $500 \mu\text{g mL}^{-1}$, it was observed 50% of the eradication of biofilms produced by *S. aureus* and *E. coli*. Already, Memar et al. (2021) evaluated the antibiofilm potential of meropenem-loaded mesoporous silica nanoparticles (MSNs) against carbapenem-resistant *P. aeruginosa* clinical isolates. In this study, it was observed that the MBICs of MSNs loaded with meropenem was $16\text{--}64 \mu\text{g mL}^{-1}$ for 10 carbapenem-resistant and biofilm-forming *P. aeruginosa*.

Prakashkumar et al. (2021) prepared palladium nanoparticles coated with neem gum (NG@Pd NPs) and observed the antibiofilm activity against MSSA. Palladium nanoparticles were coated with neem gum by simple ultrasound technique and presented an average size of 110 nm. The antibiofilm activity of NG@Pd NPs was observed, inhibiting biofilm formation by $72.73 \pm 0.015\%$ at a concentration of $40 \mu\text{g mL}^{-1}$ and more than 60% at a concentration of $20 \mu\text{g mL}^{-1}$.

Mohammadizadeh and Kashi (2021) synthesized silver nanoparticles (AgNPs) using *Trifolium pratense* L. extract as a reducing agent and tested the antibiofilm activity against antibiotic-resistant *E. coli* strains. The AgNPs had an average particle size of 19 nm. The percentage of biofilm inhibition by the silver nanoparticles was between 21.12% and 97.10%. Several studies have demonstrated the inhibition of biofilm formation in vitro in Gram-positive and Gram-negative bacteria at specific concentrations of nanoparticles. This raises the intriguing possibility of treating infections caused by biofilm-forming bacteria with inorganic nanoparticles (Mihai et al., 2018).

External physical stimuli

Nanostructures can be activated by an external stimulus that promotes controllable changes in the properties of materials by stimulating the release of antimicrobial molecules, constituting a promising alternative for the delivery of conventional and new antibacterial agents (Wolfmeier et al., 2018; Rivera-Tarazona et al., 2021).

Nanomaterials activated by external stimuli remain latent until their activation, minimizing toxic effects on normal cells and human microbiota. In addition, these nanomaterials increase the specificity for the target and improve the release of the active ingredient (Colilla and Vallet-Regí, 2020; Cheeseman et al., 2020a). The targeting of antibiotics to bacteria can be achieved by responding to external physical stimuli, such as magnetic, thermal, light and ultrasound effects (Yeh et al., 2020).

Magnetic action-activated nanomaterials allow magnetic NPs to penetrate and target the infection site to disrupt individual microorganisms and remove communities of microorganisms from surfaces helping to break and disperse the biofilm (Cheeseman et al., 2020a,b; Elbourne et al., 2020). Among the types of approach using the magnetic field, it is highlighted magnetic hyperthermia and magneto physical nanomaterials that respond to these stimuli through a localized increase in temperature and physical disruption, respectively (Cheeseman et al., 2020a; Colilla and Vallet-Regí, 2020).

Quan et al. (2019) evaluated the antibiofilm activity of gentamicin-carrying magnetic nanoparticles (MNPs-G) against biofilms of *S. aureus*. The diameters of MNPs-G were around 60 nm and after exposure of MNPs-G in a concentration of $440 \mu\text{g mL}^{-1}$ associated with a magnetic field, an eradication of more than 50% of the biofilm was observed.

Elbourne et al. (2020) produced Galinstan-based magnetic liquid metal microparticles and nanoparticles (GLM-Fe). They evaluated the antibiofilm activity against *P. aeruginosa* ATCC 27853 and *S. aureus* ATCC 25923 of GLM-Fe associated with a 775 mG dynamic magnetic field. The average particle diameter ranged from ~ 200 nm to $2 \mu\text{m}$. After 90 min of exposure of GLM-Fe at a concentration of $100 \mu\text{g mL}^{-1}$ under the effect of the magnetic field, an eradication of 99% of the biofilm of *S. aureus* and *P. aeruginosa* was observed and the infeasibility of bacterial cells was also observed.

Cheeseman et al. (2020b) produced Galio-based magnetic liquid metal microparticles and nanoparticles (GLM-Fe) and evaluated the antibiofilm activity against *P. aeruginosa* ATCC 27853, *E. coli* DH52, *Bacillus cereus* ATCC 11778 and *S. aureus* ATCC 25923 of GLM-Fe associated dynamic magnetic field of 775 mG. The average particle diameter varied from 100 nm to $1 \mu\text{m}$. After 90 min of exposure of GLM-Fe at a concentration of $100 \mu\text{g mL}^{-1}$ under the effect of the magnetic field, eradication around 80%, 99%, 95% and 0% of the biofilm of *P. aeruginosa*, *E. coli*, *S. aureus* and *B. cereus* was observed, respectively. The antibiofilm potential of these species was also observed together at a concentration of $100 \mu\text{g mL}^{-1}$, and inhibition of 95% was observed for all multispecies biofilms.

Light is the physical stimulus capable of being an external release trigger for releasing antimicrobials, constituting an attractive therapeutic option to conventional antibiotic treatments (Rivera-Tarazona et al., 2021). Photocatalytic nanomaterials are stimulated by contact with wavelengths of light to produce free reactive oxygen species (ROS), producing antimicrobial action. In contrast, photothermal nanomaterials are stimulated with the localized increase in temperature produced by light waves that interact with the materials (Cheeseman et al., 2020b; Rivera-Tarazona et al., 2021).

Bagchi et al. (2018) synthesized hybrid surface nanoparticles of squaraine/ZnO (ZnO-SQ) and evaluated the antibiofilm activity in *S. aureus* strain ATCC 25923. The particles showed a size of ~ 24 nm, and the bacterial biomass was reduced by $\sim 55\%$ when ZnO-SQ-treated bacteria were exposed to red light for 30 min at a concentration of 140 nM.

Wang et al. (2019) evaluated the antibiofilm activity of light controllable chitosan micelles loading with thymol (T-TCP) against *S. aureus* ATCC 29213. T-TCP showed particle sizes of 100.3 nm, a positive surface charge of 33.4 mV and an encapsulation efficiency of 30.8%. At the concentration of 330 $\mu\text{g mL}^{-1}$ associated with exposure to light, there was a reduction in the biofilm with the generation of ROS, simultaneous release of thymol and generation of additional ROS-inducing bactericidal effects.

Xie et al. (2020) developed gold nanoclusters functionalized with deoxyribonuclease (DNase-AuNCs) and evaluated the antibiofilm potential against *S. aureus*, *P. aeruginosa* and *E. coli* after light exposure. The particle size of 2.33 ± 0.72 nm, the zeta potential of 12.9 mV and reduction of 85.9, 82.6, and 83.4% for the biofilms of *S. aureus*, *E. coli*, and *P. aeruginosa*, were observed, respectively.

Ultrasound (US) is an external stimulus, mainly used at low frequencies, capable of targeting nanomaterials and improving the effectiveness of antibiotics. This technique increases the permeability of bacterial cell membranes to the antibiotics available in the medium (Muhammad et al., 2020). The use of low-frequency ultrasound (20–100 kHz) in the treatment of pathogenic bacterial biofilms is an important tool since they act by altering the permeability of biofilms to conventional, natural antimicrobial compounds and nanostructures (Muhammad et al., 2020; LuTheryn et al., 2020).

The mechanical oscillation generated by the US can remove polysaccharides, change the protein composition and intensify the breakdown rates of glycosidic bonds in the biofilm matrix. Additionally, it causes changes and holes in the outer membrane and cytoplasmic membrane of the bacteria. These effects can reduce the number of cells in the biofilm, damage the stable complex structures of the formed biofilm and boost the detachment of the biofilm from specific surfaces (Runyan et al., 2006; Xu et al., 2018; LuTheryn et al., 2020; Yang et al., 2019; Shao et al., 2020). Studies indicate that in vitro efficacy tests with this technique enhance the antibiofilm activity of molecules and/or antibiotics against *S. aureus*, *E. coli*, *K. pneumoniae*, *P. aeruginosa* and *A. baumannii* resistant to antimicrobials (Wang et al., 2018, 2020; Fu et al., 2019; Hou et al., 2019; Liu et al., 2020; Bharatula et al., 2020).

Fu et al. (2019) prepared liposomes containing chitosan-modified polymyxin B (CLPs) and ultrasound microbubbles (USMBs). They evaluated in vitro the antibiofilm effect of USMBs combined with CLPs against antibiotic-resistant *A. baumannii* W1340. The PLCs had a size of 225.17 ± 17.85 nm, a zeta potential of 12.64 ± 1.44 mV and drug loading of $15.62 \pm 1.97\%$. The USMBs were 2.391 ± 0.052 μm in size and had a zeta potential of -4.32 ± 0.43 mV. To assess antibiofilm activity, a frequency of 1.0 MHz for 5 min was used. The PLCs, USMBs and PMBs eradicated less than 50% of biofilms. However, the combinations of USMBs + PMB reduced around 85% and CLPs + USMBs around 95% of biofilms.

Hou et al. (2019) evaluated in vitro the effects of low-intensity and low-frequency ultrasound (LILFU) combined with tobramycin against extended-spectrum beta-lactamases (ESBLs) *E. coli* biofilms from a urine sample. The biofilms of ESBLs *E. coli* were established and treated with ultrasound (42 kHz and ISATA of 0.66 W/cm^2) continuously for 0.5 h with and without tobramycin. The combined ultrasound treatments with tobramycin at 8 $\mu\text{g mL}^{-1}$ and 80 $\mu\text{g mL}^{-1}$ reduced biofilm and increased drug permeability.

Liu et al. (2020) evaluated in vitro the association of low-frequency ultrasound (LFU) with antimicrobial agents such as meropenem (MEM), tigecycline (TGC), fosfomycin (FOM), amikacin (AMK) and colistin (COL) against biofilm of *K. pneumoniae* clinical isolates. The authors observed synergistic effects in groups of single ultrasound (S-LFU, 5 min) or multiple ultrasounds (M-LFU, 5 min every 8 h) combined with MEM, TGC and FOM.

These studies highlighted the therapeutic potential of external physical stimuli, making them promising alternatives for treating infections caused by biofilm-producing bacteria (Wolfmeier et al., 2018; Colilla and Vallet-Regí, 2020; Yeh et al., 2020).

Conclusion

Biofilms are intrinsic virulence factors in the ecology of bacteria and are essential in the biotechnological, environmental, and industrial sectors. However, this bacterial way of life can affect human health when associated with infections. Infections caused by biofilms producing-bacteria are persistent, resistant to antibacterial therapy, and are considered a global public health problem.

Conventional antibiotics therapies, such as tetracyclines, quinolones, sulfonamides, macrolides, oxazolidinones, daptomycin, rifampicin, beta-lactam antibiotics, glycopeptides, aminoglycosides or polymyxins present limitations to eradicate biofilms. This fact occurs as the organization of biofilms makes it difficult for these antimicrobials to penetrate, in addition to stimulate the development of microbial resistance.

In this sense, the use of nanomaterials to deliver active compounds within biofilms is an effective therapeutic option, since the nanostructures promote the elimination of bacterial cells and the rupture of the matrix formed by EPS creating craters in the structure of the biofilm. Associated with nanomaterials, external physical stimuli such as the magnetic field, light, and ultrasound waves, are effective methods that allow the biofilms to be disrupted and allow the conduction and greater penetration of antibiotics, natural products and nanocarriers.

Therefore, due to the growing problem of biofilm formation by strains pathogenic to human beings, it is necessary to discover products with the disruptive potential of the matrix and/or mucolytics, in parallel to the development of nanomaterials with antibacterial activity and the use of combined stimuli as an essential strategy to prevent the formation and eradicate bacterial biofilms.

Introduction

A paradigm shift in the treatment of infectious diseases is necessary to prevent antibiotics becoming obsolete, and where appropriate, alternatives to antibiotics ought to be considered.

(Carson et al., 2006).

Within a generation after antibiotic introduction, bacterial infection morbidity/mortality sharply fell. However, within a few more human generations, rapid genetic sharing of resistance genes has returned bacterial induced deaths to front and center, therefore the world again faces a crisis. Dire calls have been issued for the development of new drugs. Nevertheless, just as fast as medicines are developed, pathogens rise to resistance (see fascinating but frightening video of *Escherichia coli* developing resistance over just 11 days to 1000× inhibitory concentration at outset, [Science News, 2016](#); Baym et al., 2016).

The advent of modern medical technology has accelerated the natural evolution of microorganisms into self-serving and protective communities termed “biofilms,” notoriously resistant to conventional treatment ([Bjarnsholt, 2013](#)). Therefore, there is urgent need to resurrect old but useful therapies, which were actually curing infection prior to the drug era, which therapies went lost or forgotten. Actually, medicine, due to the successful results of pharmaceutical approaches to treat infectious diseases, has paid scant attention to harnessing the body’s own innate defenses to overcome pathogens, whether viral, bacterial, fungal, or other.

Immune cells respond to invaders with an oxidative or respiratory burst ([Nguyen et al., 2017](#); [Roos et al., 1988](#)). Macrophages and neutrophils engage, engulf, and destroy pathogens. When encountering an invader, white cells may consume up to 30× the amount of oxygen as at rest. This “burst” induces synthesis of powerful oxidants, actual germicides, enabling lysosomal dissolution of the pathogen. Such oxidants include, but are not limited to, superoxide, hydrogen peroxide, nitric oxide, hydroxyl radical, and peroxynitrate ([Prolo et al., 2014](#)). Other reactive species are sodium hypochlorite (bleach), singlet oxygen, and ozone, which is the most powerful of the oxidants, recently discovered to be endogenously generated in humans from singlet oxygen catalyzed by antibodies ([Babior et al., 2003](#)).

Might it be possible to heal infection by augmenting these natural defenses? The medical literature cited in this chapter strongly suggests this. Animal life has coexisted on the planet with bacteria for hundreds of millions of years. If bacteria could become resistant to endogenously generated germicides, we would not be here.

Ozone therapy

Ozone (O₃ or triatomic oxygen)

More than 180 years ago, in 1840, triatomic oxygen was discovered by the electrolysis of oxygen creating an odorous gas that its discoverer, Christian Schonbein, called “ozone.” Ozone was quickly discovered to destroy bacteria and within a few decades, rapidly gained fame in purifying water. Nikola Tesla patented the first American ozone generator in 1896. However, ozone’s utility was hampered at those times by lack of ozone-resistant materials, as the molecule could oxidize naturally occurring hydrocarbons turning them into carbon dioxide and water. The advent of resistant plastics rehabilitated ozone therapy into healing fields by German scientists. In 1958 pediatrician Robert Mayer (1983) of Florida published “Using Ozone as a Chemotherapeutic Agent in the Treatment of Diseases,” having learned of the therapy from a German prisoner in the Second World War. More recently, many of its mechanisms of action have been elucidated.

Generation of ozone

Ozone, a metastable pale blue gas, must be generated onsite and used quickly. Its half-life at room temperature is about 30 min, before dismutating back to O₂. O₃ resonates between four ionic structures, highly soluble in water. O₃ is generated from a high voltage corona arc discharge, similar to lightning. Medical “ozone” is actually a mixture of O₂ and O₃, 95–99% and 1–5%, respectively, or 5–70 µg ozone/cc. “Ozone” can be collected in a syringe for parenteral administration, or conducted into a bottle or bag to treat extracorporeal blood, or bubbled through water/saline to make an ozonated solution, or administered to body cavities (Elvis and Ekta, 2011; Shrisel and Suryakant, 2017; Bocci et al., 2012). The advantages and limits of each approach are reported in a subsequent paragraph. However, The U.S. Food and Drug Administration 21 CFR H (801) declares ozone to be a toxic gas with “no known useful medical applications” (FDA, 2020). This “statement” remains in the federal regulations despite thousands of scientific publications, including positive biochemical/metabolic effects in vivo (including humans), highlighting the benefits of ozone therapy. Indeed, ozone gas, when inhaled directly, can damage lungs; therefore, the system used in antimicrobial therapy must not permit leaks which could lead to inhalation. The lungs are singularly highly ozone sensitive.

Ozone antibacterial/antiviral properties

Ozone virtually instantly destroys bacteria, about 100 times faster than chlorine. Unlike chlorine, it leaves no toxic residue. Furthermore, it quickly cuts through and destroys biofilms (Bialoszewski et al., 2011) that are virtually impossible to treat conventionally. Ozone can also be used to control tuberculosis in diabetic patients.

Multiple reports demonstrate the need for viral envelope glycoproteins to be reduced (R-S-H rather than oxidized R-S-S-R) to enter cells, including Ebola (Chandran et al., 2008; Lee and Saphire, 2009) and coronavirus (Broer et al., 2006; Schoeman and Fielding, 2019; Lopez et al., 2008). CMV loses infectivity when oxidized, but 65% is restorable if chemically rereduced (Mirazimi et al., 1999). Many viruses including cytomegalovirus, HIV, Norwalk, bacteriophage MS2, hepatitis A, and poliovirus are nearly instantly inactivated by ozone (Wolf, 2019; Kekez and Sattar, 1997; Herbold et al., 1989; Emerson et al., 1982; Katzenelson et al., 1979; Roy et al., 1981b; Roy et al., 1981a). HIV cell entry is dependent on reduced thiol groups (Ryser et al., 1994; Markovic et al., 2004).

In vivo, ozone instantly reacts with blood components, extinguishing the delivered ozone, leaving only useful O₂ as a residue. The temporary oxidative stress generates reactive oxygen species (peroxides, aldehydes, etc.), which chemically are more electrophilic than sulfur, hence oxidizing the fragile viral thiol groups ($\text{ROOH} + 2 \text{RSH} \rightarrow \text{R-SSR} + \text{H}_2\text{O}$). As an example, coronavirus spike proteins are rich in sulfhydryl groups and tryptophan (Broer et al., 2006), both very susceptible to oxidative damage (Sharma and Graham, 2010). Therefore, virions are inactivated while retaining their immunogenicity, thus speeding up infection resolution and enhancing natural resistance. Ozone may also damage the lipid component of enveloped virions, a desired effect since viruses cannot self-repair the damaged structures. Lorizate and Kräusslich (2011) discussed that agents that attack the lipid envelope could be useful as antivirals. However, they lamented that conventional agents lack specificity and are “thus unacceptably toxic.” Ozone therapy does not so suffer.

Ozone biochemical and immune modulating effects

O₃ is a most powerful oxidant. Two research teams (Italy and Cuba) have independently found major biochemical modulations induced by ozone (Bocci, 2011; Menéndez and Weiser, 2016). Among these effects are: (1) increased red blood cell 2,3 diglycerophosphate (greater hemoglobin oxygen release), (2) improved rheological properties of red blood cells and endothelial nitric oxide production, (3) greater arterial/venous partial O₂ pressure difference, indicating greater mitochondrial consumption of oxygen (energy production), (4) immune system modulation and reduction of inflammation, (5) improvement of antioxidant status, antioxidant enzymes (including superoxide dismutase), and glutathione in cells.

All these effects are achieved by ozone virtually instantly reacting with unsaturated (electron rich) fatty acids and generating ozonides, which act as downstream cell signaling redox molecules and other shorter lived ROS (reactive oxygen species: peroxides, aldehydes, etc.). These affect and modulate redox status without altering blood cell membranes (Bocci, 2011; Menéndez and Weiser,

2016). The authors reported that damage to red cell membranes required higher concentrations of ozone (over 80 µg/cc) than clinically used (15–70 µg/cc). Significant hemolysis has not been reported with any form of ozone therapy.

Conventional thought is that oxidative stress is negative for human health. However, unlike pathological oxidative stress, the controlled oxidative processes of ozone actually induce antioxidant enzyme production. In particular, ozone activates the Nrf2 (nuclear factor erythroid) protein, which activates many protective enzyme pathways (Galiè et al., 2019). In activating the Nrf2 pathway in human multiple sclerosis patients, ozone induces higher levels of antioxidant enzymes, and lower pro-inflammatory peptides TNF α and IL-1 β (Delgado-Roche et al., 2017). Ozone also induces heme oxygenase (Pecorelli et al., 2013).

It has been established that the ozone's hydrogen peroxide-mediated natural induction of cytokines by immune cells is safer and more effective than exogenous administration of a single cytokine. Bocci (2011) called ozone the “ideal cytokine inducer” and described ozone-treated erythrocytes as “super gifted,” in reference to their enhanced ability to deliver oxygen (their specific function).

Cuban research has demonstrated valuable properties of ozone therapy in infection.

Preconditioning with ozone (ozone treatment before inflicted infection) improved survival of rats to subsequent lethal peritoneal injection of fecal material up to 62.5%. Such preconditioning also rivaled steroids in reducing tumor necrosis factor alpha release in endotoxic shock (Zamora et al., 2005). When antibiotics were added to ozone preconditioning, survival increased to 93% (Bette et al., 2006). Ozone therapy induces prostacyclin production, improving the prostacyclin/thromboxane ratio (Schulz et al., 2012), which would have a positive effect on circulation and reduction in inflammation.

Ozone safety

The largest safety study was conducted in 1980 by Jacobs (1982) for the German Medical Society for Ozone Therapy. She surveyed 2815 known European ozone therapists with a 25% response rate. The report tallied 384,775 patients and 5,579,238 ozone treatments. The risk of adverse incidents was only 0.7 per 100,000 treatments, often related to improper administration. Pediatrician Robert Mayer (1983) reported on 3000 administrations (including intrathecal ozone gas for meningitis), most in children. Mayer found ozone “without any side effects or toxicity noted.” Robins (2018) reported performing over 300,000 ozone treatments utilizing direct intravenous gas (DIV) with no lasting ill effects other than vein irritation with this particular method. Rowen (2016) conducted and presented a survey of those he has trained in a delivery method called “hyperbaric ozone.” No significant adverse problems reported in 30,000+ observed treatments. Ozone therapy appears to be one of the safest, if not the safest, treatment modalities ever known.

Delivery methods, advantages, and disadvantages

Ozone must be generated on site as its half-life at room temperature is about 30 min. Inhalation must be avoided/minimized. The lungs have very limited capacity to handle such powerful oxidative stress, considering that even breathing 100% O₂ for prolonged periods can be harmful to pulmonary tissues. However, although ozone gas cannot be inhaled, it can be safely bubbled or nebulized through oils for inhalation. This method was used in America's early ozone days, often to reduce tuberculosis organisms in lungs (Eberhart, 1913).

Nevertheless, medical reports suggest that ozone administered to any other body tissue is safe. The most common sites of delivery are to blood, joints, soft tissues, body cavities, subcutaneous, and intramuscular (Bocci, 2011; Menéndez and Weiser, 2016). Delivery is via direct gas injection, gas insufflation, drinking ozonated water, topical, and autohemotherapy (patient's blood treated with ozone outside the body and returned). Local treatments are applied for local conditions.

Ozone gas can be administered into body cavities and spaces such as bladder and joints. For bladder, the volume ranges from 10 cc to 60 cc based on condition, size of patient, and comfort. Concentration of gas ranges between 10 and 40 µg/cc (Bayrak et al., 2014). Joint therapy is universally well accepted to be effective for degenerative and inflammatory joint conditions (Trevisani and Udell, 2015). Typical treatment is preloading the joint (or soft tissue) with a small amount of local anesthetic (preservative and epinephrine free), followed by ozone gas at a concentration of 15–40 µg/cc. A usual knee treatment delivers 10–20 cc. Because ozone is germicidal and antibiotic resistance is not an issue, any type of infection can be treated.

Rectal administration is very inexpensive to administer at home, leaving little or no medical waste. Menendez and Weiser (2016) led Cuban studies indicated that this mode induces similar biochemical effects in the body as blood therapies. This mode improved COVID-19 disease reducing inflammatory markers of fibrinogen, D-dimer, urea, ferritin, LDH, IL-6, and CRP (Fernández-Cuadros et al., 2020).

The dosage depends on the body size of patient, 50–400 cc (volume increased as tolerated) beginning with concentration of 20 µg/cc and increasing to 40–45 µg/cc, as tolerated. The treatment can be performed a few times a week to even 3–4 times daily depending on need. It is generally applied by filling a plastic IV bag with ozone gas, attaching its outlet tube to a reusable catheter, which is placed in the rectum, and the bag contents slowly rolled in. The gas induces a significant bowel evacuation within minutes in most people. However, clinical results are not as rapid or effective, per treatment, as auto-hemotherapy (extracorporeal treatment of blood, which is then returned).

Systemic therapies are used for systemic conditions. There are no published reports of problems in combining methods. The most common systemic delivery method worldwide is direct venous gas (DIV) application. Intravenous oxygen gas therapy has been employed in Europe for generations and has been found to modulate the immune system through generation of 15-Lox-1 by

eosinophils (Chaitidis et al., 2004), and improve prostacyclin production (Stichtenoth et al., 2001). Intravenous oxygen gas therapy has been reported to induce strong immunological effects and improve blood rheology and oxygenation (Schmidt, 2002). DIV ozone is very inexpensive to deliver, requiring (aside from the ozone generator) only a syringe and fine butterfly needle, with minimum medical waste. Hence, DIV has great advantage in the third world where the method is most used. However, the presence of ozone, a powerful oxidant, in the gas mixture, can be irritating to veins and repeated use can lead to vein sclerosis. Dosage generally begins with 20 ccs of gas at concentration of 30–40 µg/cc with increase in volume as tolerated to 100 cc or more. DIV training is important before beginning. Some ozone users in western countries have opposed DIV fearing gas embolism after intravenous administration (Madrid, 2020). However, the gas is not air, which contains about 80% nitrogen, but 100% metabolically active oxygen (O₂/O₃ mixture), which is rapidly consumed.

The most popular delivery in the Western world is major autohemotherapy, which has two modes. The simplest is performed by withdrawing 50–200 cc heparinized blood into a plastic bag under gravity. An equal amount by volume of ozone gas, 20–70 µg/cc, is added and mixed with the blood by gentle rocking. The treated blood is then returned to the patient by gravity (total time about 2 h). Inert glass bottles are preferable to plastic.

A superior method is performed by using a glass evacuated bottle to withdraw up to 200 cc of blood. An equal amount of ozone gas is pumped into the bottle under up to two atmospheres of pressure (2 ATA), mixed, and then rapidly returned to the patient by the pressure. Although there is need for a more sophisticated ozone generator, this method has the advantage of more thorough admixing of gas and blood, and the delivery of actual solubilized oxygen gas in the returned blood, which, as mentioned above, has additional beneficial effects. Hyperbaric ozone therapy is far quicker (10–15 min/treatment) than gravity method. Furthermore, the hyperbaric ozone method (HBO₃) has the additional advantage of permitting additional “passes” of 200 cc of blood up to 10 passes or more, as pioneered by Johann Lahodny, MD of Austria (2017), who called this method “Ozone High Dose Therapy” (OHT), known in America as “10 pass.” Very rapid clinical improvement in infected patients has been reported (American Academy, 2017). The disadvantage of both autohemotherapy methods is medical waste.

Ozone minor autohemotherapy is administered by withdrawing up to 10 cc of blood in a syringe prefilled with an equal amount of ozone gas at a desired concentration. The entire mixture is vigorously shaken and quickly returned intramuscular (IM). Bocci (2011) considered IM ozone as an immune stimulant and modulator. Ozone gas can be given directly IM, concentration up to 20 µg/cc with little discomfort. Generally, up to 20 cc of gas is injected. Likewise, the gas can be given to local skin infections, including warts, by subcutaneous route (Bocci, 2011).

Ozone treatment of human acute bacterial infections

Bacteria are virtually instantly destroyed by ozone gas exposure. However, except by local gas injection into a focal infection, all the effects of ozone therapy will be indirect and secondary to its profound modulation of biochemical processes and induction of downstream ozonide metabolites (Bocci, 2011; Menéndez and Weiser, 2016). While we lack desirable infection “double blinded” studies, many reports demonstrate that ozone can be an effective alternative or adjunctive therapy to current conventional drug practices. Local ozone injection and HBO₃ together with an oral antibiotic treatment were reported as the first medical treatment to successfully eradicate a prosthetic joint infection without surgery or parenteral antibiotics (Rowen, 2018a). Single treatment of HBO₃ alone eradicated a tick bite cellulitis in a man previously cleared of Lyme disease years before by HBO₃ without antibiotics (Rowen, 2018b). Used in combination with antibiotics, ozone was reported to prevent resistance to drugs in *Mycobacterium tuberculosis* in humans (Belianin, 1997; Belianin and Shmelev, 1998). Ozone therapy, in conjunction with removal of infected teeth, remitted a highly aggressive case of dermatomyositis (Rowen, 2018c). Topical ozone therapy induced a highly significant reduction in erythrocyte sedimentation rate in osteomyelitis patients compared to control group, though clinical outcomes were similar in both groups (Naderi Nabi et al. (2018). Topical application of ozonized oil has been used successfully against *Staphylococcus aureus*, including MRSA (Song et al., 2018).

Ozone therapy in human viral disease

Medicine has serious challenges in addressing viral diseases. Nevertheless, viruses have particular vulnerabilities to oxidation, as referred in a previous section. Rowen speculated that ozone therapy may be the ideal treatment for controlling viruses, summarizing viral inactivation by oxidation (Rowen, 2019).

Virions can be inactivated by ozone/ozonides while retaining their immunogenicity, quickening infection resolution and enhancing natural resistance. Outstanding clinical effectiveness of ozone therapy has been reported in meetings of ozone doctors sharing clinical work worldwide and in clinical case series of Ebola (Rowen et al., 2016) and coronavirus (Wu et al., 2020; Franzini et al., 2020).

Ozone in pediatric infections

Pediatrician Robert Mayer (1983) reported results from 1946 to 1964 of significant research on 2870 children. In summary, for nonbacterial infectious diarrhea, 1932 resolved multiple days of diarrhea, most in just one day, with one rectal insufflation of gas. He also reported data on intrathecal ozone for 5 viral (mumps, rubeola, St. Louis encephalitis) and two bacterial (*Francisella tularensis* and *Pseudomonas aeruginosa*) meningitis cases. All patients recovered except one; however, the low numbers prevent any statistical consideration. However, the case concerning *P. aeruginosa* is worth mentioning. This was a two-month premature infant, who, on day 5, developed overt meningitis, with spinal fluid WBC count of 13,600. *P. aeruginosa* was detected after culture. The child

received numerous antibiotics, and by day 13, spinal fluid WBC dropped to 450 with still a positive culture. The drugs were discontinued. Mayer provided intrathecal ozone at 89 µg/cc by first removing spinal fluid equal to the volume of gas to be injected. Twelve administrations were performed (intraspinally and intracisternal). The child fully recovered having normal milestones through a year's observations.

Topical ozone

Ozone has been used for decades in several methods of delivery: bathing a wound with the gas in bags, topical application of ozonized water or saline, and ozonized oil. Unsaturated bonds of fatty acids can trap O₃ holding it with stability for months/years. Ozonized vegetable oil has been found to destroy microbes with particular efficacy against *Mycobacterium*, presumably because of its susceptible waxy (fatty) vulnerable coat, and MRSA (Sechi, 2001). The mechanism is a germicidal effect. Lavage by ozonated saline solution proved the most effective irrigating solution (even over antibiotic solution) to prevent bacterial abscess formation in experimental peritonitis rat model (Ozmen et al., 1993). Many oils are available commercially. Saline or aqueous solutions must be made fresh due to dismutation of the dissolved raw gas.

Topical (by bag) and parenteral ozone application was added to a failed antibiotic and debridement regimen for seriously advanced wound infection, with 4/5 of tibia exposed, and pus extruding from knee joint with full resolution (Shah et al., 2011).

Ozone applications have been used successfully as a disinfectant in dentistry for many years. These include ozonized water, ozonized oils, and local injections. These have proven to be antimicrobial, immunostimulating, analgesic, and with no toxic effects on the local tissue environment. This results in a promising approach for “green dentistry” (Nagarakanti and Athuluru, 2011; Mobeen, 2017).

Ultraviolet blood irradiation (UBI)

Historical background

Termed “The Cure That Time Forgot” (Rowen, 1996), UBI has been used continuously in America and overseas for many generations. Ultraviolet energy is a known germicide, used topically at the turn of the last century to cure skin infections. The 1904 Nobel Prize in Physiology or Medicine was awarded to Niels Finsen for his work on UV treatment of various skin diseases. His success rate was 98% in thousands of cases, mostly cutaneous tuberculosis known as lupus vulgaris. Walter Ude reported a series of 100 cases of erysipelas (a cutaneous infection caused by *Streptococcus pyogenes*) in the 1920s, with high cure rates using irradiation of the skin with UV light (Ude, 1929).

American physicist Emmett Knott assembled the known information, and developed a device to irradiate blood extracorporeally. Experimenting on dogs, he settled on a dose of 3.5 cc blood per kg weight and specific exposure times (10 s per aliquot of blood) using a water-cooled boiling mercury bulb emitting 200 watts of energy. The key to the Knott's method was a quartz glass chamber, which induced turbulence to assure maximum exposure to the treated blood. Otherwise, the first few exposed cell layers would absorb all the UV energy. A woman with a septic abortion received the first human treatment. She survived and went on to have two children. Following this case, and availability of his machine, dozens of articles appeared in American literature detailing extremely rapid and stunning resolutions of otherwise (at that time) untreatable bacterial and viral infections (Miley and Christensen, 1948; Barrett, 1940). Most cases resolved in 1–2 sessions. No toxicity was reported in thousands of treatments.

Typical sepsis fever curves and clinical outcomes from UBI therapy, no antibiotics (Rebbeck and Miley, 1941):

UBI was used to treat incomplete septic abortion, puerperal sepsis, acute pyelitis, peritonitis, sepsis, osteomyelitis, wound infections, and infectious thrombophlebitis. In 1947, George Miley and his team summarized 445 cases of acute pyogenic infection, including 151 consecutive cases (Miley and Christensen, 1947). Results showed a 100% recovery in 56 early cases, 98% recovery in 323 moderately advanced cases, and 45% in 66 apparently moribund patients (Table 1). Staphylococcal infections were also successfully treated, providing that sulfa drugs were not simultaneously used, since the sulfa nucleus absorbs UV photons and interferes with the UBI therapy (Miley, 1944).

UBI was reported highly effective in viral pneumonia, hepatitis, polio (Miley and Christensen, 1948), and even Clostridia caused botulism (Miley, 1946).

Table 1 Results in 445 cases of acute pyogenic infection given ultraviolet blood irradiation therapy at the Hahnemann hospital, Philadelphia, over a period of six and one-half years.

	<i>No. of cases</i>	<i>Recovered</i>	<i>Died</i>
Early			
Puerperal sepsis	3	3	
Incomplete septic abortion	12	12	
Acute furunculosis and carbunculosis	15	15	
Abscesses	2	2

Summary			
Number of cases	Early 56	Moderately Advanced 323	Apparently Moribund 66
Number recovered	56	317	30
Percentage recovered	100%	98%	45%

Mechanism of action

UBI efficacy appeared to be consistent with a hormetic effect. Only about 5% of the blood volume was treated; therefore, the effect is not linked to blood sterilization. American physicians reported the following effects from UBI: toxin inactivation, bacteriostatic or bactericidal effect on bacteria, improvement of blood oxygen transport, leukocyte activation, immune stimulation, steroid hormone activation, vasodilation, reduced platelet aggregation, fibrinolysis, decreased blood viscosity, and improved microcirculation (Rowen, 1996). These effects singly and collectively would assist physiology in infection.

Still (2021) functioning Knott Hemo-irradiator, circa 1958

UBI in America largely faded with the advent of pharmaceutical antibiotics but continued in Germany and Russia with the development of less powerful but easily accessible devices (Douglass, 2003; Frick, 1986).

Germans found several metabolic effects, which mirror current findings in ozone therapy biochemistry. Seng (1988) reported the following effects from UBI therapy: (1) improves RBC rheology; (2) increases negative charge across RBC membrane; (3) reduces blood surface tension and platelet aggregation, while raising blood cells number; (4) increases the Pa-Pv O₂ difference and reduces blood pyruvate and lactate [suggesting improved mitochondrial activity]; (5) improves glucose tolerance; (6) reduces blood cholesterol, transaminases, and creatinine values; and (7) increases WBC phagocytosis and bactericidal blood capacity. A typical treatment today uses 60–200 cc of blood, passing it whole or diluted in saline through a quartz glass cuvette exposed to UV energy.

Analogies with ozone treatment

Ozone and UBI therapies have much in common. UV-C frequencies (253 nm) used in therapy are similar to the UV-C radiation that creates ozone naturally in the upper atmosphere. Conversely, ozone releases energy (a photon) when dismutating back to oxygen. Both quickly destroy pathogens and modulate immune function. Positive effects of both treatments can be achieved treating only 5–7% of blood. Better understanding the role of oxidation-related effects exerted by UBI in blood clearly links this treatment with ozone therapy. UBI has been shown to increase white blood cell production of hydrogen peroxide (Ivanov et al., 1989) (as does ozone). Almost identical to the findings of Bocci (2011) and Menendez and Weiser (2016) with ozone, UBI has been found to “highly increase” SOD and glutathione peroxidase while significantly decreasing signals of free radical damage (Dong et al., 2000). UBI may inactivate viral particles (since unlike host cells, viruses do not have repair mechanisms for genetic damage) meanwhile preserving immunogenicity. Furthermore, the cytokine storm that surrounds severe viral infections (Ebola, COVID-19) may be controlled by immune modulation that both these therapies provide (Hamblin, 2017). Ozone’s huge advantage over UBI is that it can be locally administered to infected or compromised tissues improving local hypoxia in addition to its other stimulatory effects.

Intravenous hydrogen peroxide therapy

In the 1918 Spanish influenza epidemic, tens of millions died, predominantly of viral pneumonia. There was no treatment then, and little treatment still today for serious viral infections. British physician Oliver in India nearly halved the mortality of viral pneumonia with intravenous hydrogen peroxide. He emphasized that only the worst cases were so treated (Oliver and Murphy, 1920). In the 1980s Charles Farr, conducted informal studies utilizing a 0.03% H₂O₂ concentration in 250 cc 5% dextrose, infused over 1.5 h. The infusions were found to be safe and effectively shortened the duration of seasonal flu illnesses. He taught hundreds of physicians his methods and, to date, no adverse effects have been reported, except peripheral vein irritation (Farr, 1994). The method releases about 25 cc of oxygen gas intravenously. Nascent oxygen released by the infusion is postulated to create a pro-oxidant blood status, creating similar redox messenger molecules as ozone therapy, UBI, and high dose IV Vitamin C. The common protocol is twice weekly for 2–3 weeks, whether viral or bacterial disease.

However, since endothelial cells lack catalase, there is risk of local vein sclerosis at the administration site (as can high dose intravenous ascorbate), and repeated DIV ozone. As a result, H₂O₂ therapy has fallen out of favor among oxidation practitioners, replaced by ozone therapy and UBI. Nevertheless, based on Oliver’s work, it may be a lifesaving treatment when another therapy is not possible or available. H₂O₂ can also be administered by a nebulizer (0.06% to 1% in water or saline solution) especially useful in case of pulmonary disease, including COVID-19 (Brownstein et al., 2020).

Hyperbaric oxygen therapy (HBOT)

HBOT is used as either a primary or adjunctive treatment in the management of infections such as gas gangrene, necrotizing fasciitis, diabetic foot infections, refractory osteomyelitis, neurosurgical infections, and fungal infections. HBOT acts as a bactericidal/bacteriostatic agent against anaerobic bacteria by increasing the formation of free oxygen radicals. HBOT restores the bacterial-killing capacity of leukocytes in hypoxic wounds by increasing tissue oxygen tensions (Cimşit et al., 2009).

Like ozone therapy, HBOT works synergistically with conventional antibiotics. One mechanism may be similar to ozone therapy. Breathing 100% oxygen at greater than atmospheric pressure (1 ATA) increases the formation of reactive oxygen species (ROS) (Korpinar and Uzun, 2019). This will create active signaling molecules from immune cells, while being directly active against pathogens. Considering its utility in several aforementioned serious infections, HBOT could be employed in any serious infection as an adjunctive therapy. As oxygen availability and utilization is the most important factor in biological processes, and infection can compromise blood flow, HBOT, by dissolving oxygen in body fluids, may overcome this local or systemic oxygen deprivation.

Typical use is daily at 2–3 ATA, for 1–2 h, until resolution of infection. Complications can include diving-like injury to the eardrum. Oxygen toxicity risk is low due to the relatively short lung exposure to high oxygen tension.

High-dose intravenous ascorbic acid

Ascorbic acid/ascorbate (commonly called “vitamin C”) at low doses is an antioxidant acting as an electron donor. High-dose intravenous ascorbate acts as a prodrug for H_2O_2 generation (Chen et al., 2005), explaining observations over decades of its clinical utility in infection.

Septic patients have low circulating ascorbate levels (Wilson and Wu, 2012). Parenteral administration of ascorbate (10–50 g) raises plasma and tissue concentrations and may decrease morbidity.

Mechanism of action

In animal models of sepsis, intravenous ascorbate injection increases survival and protects several microvascular functions: capillary blood flow, microvascular permeability barrier, and arteriolar responsiveness to vasoconstrictors and vasodilators (Kuhn et al., 2018). The effects of parenteral ascorbate on microvascular function are both rapid and persistent. Ascorbate quickly accumulates in microvascular endothelial cells, scavenges reactive oxygen species, and acts through tetrahydrobiopterin to stimulate nitric oxide (NO) production by endothelial nitric oxide synthase, a normal and necessary process (Mortensen and Lykkesfeldt, 2014). However, sepsis can induce high levels of NO by other mechanisms, which can inhibit neutrophil migration and adhesion, and contribute to multiple organ dysfunction (Spiller et al., 2019). Ascorbate may attenuate the effects of excess NO in sepsis and offer organ protection (Oudemans-van Straaten et al., 2014).

Ascorbate may be a valuable adjuvant therapy in sepsis (Wilson, 2009). Ascorbate is important for immune cells, enhancing chemotaxis, ROS generation, and phagocytic destruction of microbes, being also required for apoptosis and clean-up of spent neutrophils. Deficiency results in impaired immunity. High doses (200 mg daily) reduce the severity and duration of the common cold (Carr and Maggini, 2017).

Infection raises metabolic demand for ascorbate. Healthy people may experience loose stools when exceeding 4–8 g orally daily. However, sick patients can tolerate intakes to 200 g daily without any GI distress, indicating far greater need and consumption tolerance of ascorbate when ill (Cathcart, 1981).

Clinical efficacy

Klenner (1949) was one of the first physicians to inject patients with high ascorbate doses. He reported in the 1950s his experiences with parenteral ascorbate, buffering ascorbic acid with sodium bicarbonate to neutralize pH. His schedule for home patients was “2,000 mg (injection) every six hours, supplemented by 1,000–2,000 mg orally every two hours.” That amounted to 8000 mg IM, plus oral amounts (depending on sleep time) from 16,000 to 32,000 mg. Klenner reported stunning rapid and complete resolutions of viral diseases inclusive of 60 of 60 polio cases. Patients were often clinically well after 72 h.

Klenner reported on even higher doses ranging from 350 to 1200 mg per kg body weight to treat illness using parenteral ascorbate to cure measles, herpes simplex, viral encephalitis, and mononucleosis. He emphasized the need to maintain continuous high levels during the acute phase of the infection. Small children were given 2–3 g IM every two hours in the buttocks. Large doses, up to 60 g, could be added to 500 cc water together with other vitamins such as 500 mg thiamin HCl, 300 mg pyridoxine, 400 mg calcium pantothenate, 100 mg riboflavin, and 300 mg niacinamide, given once or twice daily.

Typical applications would be 25 g of ascorbate (buffered to neutral pH) into 500 ml of sterile water (18 cc diluent to each gram of ascorbate are necessary to ensure correct osmolality). He reported clearing viral pneumonia easily with parenteral treatments. Klenner also gave alkaline drinks to slow ascorbate renal excretion. With 350–400 mg/kg ascorbate every 2 h, he reported quick resolution of measles and chicken pox, sometimes requiring only a few treatments. Complications included vein irritation (IV route), subcutaneous thickening (local injections). Large oral doses could cause diarrhea, and genital or anal rash and itch (Smith, n.d.;

Klenner, 1971). To prevent these effects, Klenner often added small amounts of IM corticosteroids (desoxycorticosterone), 2.5 mg for children and 5 mg for adults. This combination therapy has been reconsidered in 2017 by Prof. Paul Marik who reported that intravenous vitamin C (1.5 g) with hydrocortisone (50 mg) and intravenous thiamine (200 mg) can reduce sepsis mortality from 40% to about 8% (Marik et al., 2016).

Conclusions

Generation of reactive oxygen species (ROS) may be promising for modulating the immune system and controlling infections, including those caused by drug-resistant organisms. Ozone therapy, Ultraviolet Blood Irradiation Therapy, intravenous ascorbate, H_2O_2 , as well as Hyperbaric Oxygen Therapy are interesting therapies to be explored and exploited both as alternatives to, or in association with antimicrobials, providing that very uncommon side effects are kept in mind.

However, it should be emphasized that an important role in infection control is played by the innate immune defenses, and that the latter can be boosted not only with oxidants but also with correct nutrition. Vitamin A, zinc, iodine, and folate deficiencies, affecting 2 billion people in developing countries, impair the immune response, being a major contributor to severe infections and death (Katona and Katona-Apte, 2008). Micronutrient deficiencies (vitamins and minerals) are also common in the USA (Medical Economics, 2016; CDC.gov, 2012). Vitamins (A, B12, C, D, E, essential fatty acids) are important for ensuring the first defenses at the mucosal barrier level. Metals like zinc, iron, copper, and selenium all contribute to a correct catalytic/enzymatic activity ultimately helping immune functions. Besides these evident nutritional deficiencies, incorrect diet can alter immune defenses. As an example, the ingestion of simple carbohydrates, such as monosaccharides, can decrease the phagocytic index (Sanchez et al., 1973). Also, heavy metals (present from contamination or unwanted agricultural residues) can impair the immune system and reduce host resistance to invading pathogens (Lehmann et al., 2011; Fenga et al., 2017). Simultaneously, some foods possess useful antibacterial properties, due to their polyphenolic or other compounds. Among these are manuka honey (Johnston et al., 2018) and olive polyphenols. The latter displays antiviral activity in vitro (Bisignano et al., 1999; Rounds et al., 2012) including HIV (Bedoya et al., 2016) and SARS-CoV-2 transmission (Ergoren et al., 2020). In these changing times when important challenges such as multiple drug resistance arise, exploring new strategies to counteract infection is an urgent issue. Unfortunately, only few quantitative studies on old methods or alternative plant molecules are available in the literature. This may be because in vivo studies are expensive; and the final result, although successful, is not patentable. However, the natural world is rich in molecules that can have activity against microbes. The time is ripe to extend detailed and quantitative investigation to the myriad of compounds that can be used alone or in synergy with antibiotics or oxidation therapies. These sometimes “unapproved” but potentially lifesaving therapies can be the key for treating conventionally untreatable patients.

Introduction

In 1890, von Behring and Kitasato demonstrated that the serum of rabbits immunized with tetanus toxin contained activity against tetanus, and such serum transferred to rabbits protected them against the disease (Eibl, 2008). Techniques developed by Cohn in Boston led to the development of the separation of plasma proteins into individual stable fractions with varied biologic functions (Cohn et al., 1940). The basis for Cohn's fractionation was to use low concentrations of alcohol by reducing the pH and lowering ionic strength (Cohn et al., 1940). This procedure was performed at low temperatures, reducing the likelihood of contamination, and made large-scale fractionation possible (Cohn et al., 1940). The method is basically in use, and the produced immunoglobulin preparation contains mostly, or almost exclusively IgG with only trace amounts of IgA and IgM. In the beginning, this "Cohn fraction II" was commercially available as a 16.5% solution with glycine and Merthiolate as stabilizer and preservative (Eibl, 2008; Cohn et al., 1940). The first patient described with agammaglobulinemia by Bruton received subcutaneous immunoglobulin (SCIG) with good response (Bruton, 1952). Although Dr. Bruton started the subcutaneous immunoglobulin, the regimen was altered by himself into weekly intramuscular administration, and it became the mode of administration for more than 20 years (Bruton, 1952; Rosen and Janeway, 1966). Numerous patients with hypogammaglobulinemia were identified and treated with immunoglobulins. Initially, immunoglobulin was derived by fractionation from pools of plasma obtained from at least 500 donors, nowadays is standard to obtain it from thousands of donors (Rosen and Janeway, 1966). Early attempts to give the product intravenously were abandoned because this route had many side effects, probably due to the large amounts of Ig aggregates and highly active contaminants like bradykinin in the product (Rosen and Janeway, 1966; McCue et al., 1986). The intramuscular route was very painful and full of adverse reactions such as nausea, vomiting, and hypotension, and normal IgG levels could not be achieved by this route (Stiehm, 1984). Purification with anion exchange chromatography led to the production of intravenous immunoglobulin (IVIG) containing native IgG and throughout the 1980s and 1990s, IVIG administration was the most common method of replacement in most countries (McCue et al., 1986; Stiehm, 1984). In the 1980s the concept of immunomodulatory dose of IVIG was born from the study by Dr. Paul Imbach in Immune Thrombocytopenic Purpura (ITP) (Imbach et al., 1981).

In 1980 Dr. Berger reintroduced slow subcutaneous infusion for primary immunodeficiency disorders (recently called inborn errors of immunity (IEI)) but the method didn't gain wide enthusiasm owing to the slow rate of infusion (Berger et al., 1980; Roord et al., 1982). In 1991 rapid infusion of subcutaneous immunoglobulin was described by Gardulf and Hammastrom and with this method, good serum levels were achieved. Subcutaneous IgG (SCIG) has become established as a well-tolerated and effective treatment that is preferred by many patients (Gardulf et al., 1991; Jolles et al., 2015; Misbah et al., 2009). A limitation of SCIG use is the large volumes needed to be administered and due to the inability of tissue to accept large volumes, frequent administration at multiple sites is necessary. A novel administration strategy of immunoglobulin treatment is by injection of recombinant human hyaluronidase with subcutaneous immunoglobulins, the facilitated subcutaneous immunoglobulin (fSCIG) (Wasserman, 2014). The enzyme facilitates drug dispersion and adsorption, allowing higher IgG injection rates, bioavailability, and increased infusion volumes. fSCIG is injected less frequently compared with SCIG (1–2 weeks vs. monthly infusions).

Mechanisms of action

IgG replacement therapy (IgRT) has an essential role in minimizing infections and improving the quality of life in patients with immunodeficiency, who would otherwise suffer from recurrent infections. The large donor pool ensures the diversity of antibody

Fig. 1 Examples of some of the diverse mechanisms of action of IVIG.

repertoires that include antibody specificities to a wide spectrum of antigens (Kaveri et al., 2011). The mechanisms for the therapeutic effects of IgG products are varied and complex with new mechanisms of action being discovered continuously (Fig. 1). The presence of F(ab') fragments in the product provide antigen recognition function, whereas the Fc fragments enable activation of immunity (Matucci et al., 2015). The mechanisms associated with infection rate reduction are thought to be mainly associated with the passive transfer of pathogen-specific antibodies which neutralize pathogens and toxins or mark them for lysis (Fig. 1). Also, several lines of experimental evidence suggest that the therapeutic beneficial effects of IVIG in immunodeficiencies reflect an active role for IVIG rather than a mere passive transfer of antibodies (Kaveri et al., 2011). IVIG exercises a stimulatory effect on maturation of dendritic cells at replacement low dose (Kaveri et al., 2011). IVIG also at replacement dose induces proliferation and immunoglobulin synthesis from B-cells of CVID patients (Kaveri et al., 2011; Bayry et al., 2011).

Multiple mechanisms of action have been proposed to be responsible for the efficacy of high-dose IVIG in autoimmune diseases and different mechanisms may be important in different disease states (Fig. 1). IVIG exerts its immunoregulatory functions at multiple levels involving modulation of expression and function of Fc receptors, blocking of complement activation, interference with the cytokine profiles, modulation of idiotype network, and cell proliferation (Shock et al., 2020). High dose IVIG may implicate saturation of FcRn leading to increased clearance of pathogenic autoantibodies (Hansen and Balthasar, 2002).

IVIG also contains antibodies that occur in the absence of pathological conditions referred to as natural antibodies (Maddur et al., 2020). These antibodies are present in the absence of immunization or infection, and some of them interact with self-antigens and are called natural autoantibodies (nAAb) (Avrameas et al., 2008). These nAAb are polyreactive and are thought to play a role in neutralizing toxins, remove self-molecules, and modulating antigen presentation contributing to cellular homeostasis (Maddur et al., 2020; Avrameas et al., 2008). Of interest is that SCIG also appears to present immunomodulatory properties, although its mechanisms of action are at the moment elusive and might be similar to those of IVIG (Scheuerlein et al., 2018; Sala et al., 2018).

Indications and clinical efficacy

The goal of long-term IgG replacement therapy is to reduce the incidence and severity of infections and prevent long-term deterioration in organ function. IVIG is increasingly being recognized as a treatment option for several diseases, beyond replacement therapy for antibody defects. The following categories classify the most frequent uses of IVIG, but clinical applications continue to evolve.

Treatment of primary immunodeficiency states/inborn errors of immunity (IEI)

Patients with IEI with antibody defects, either in production or function, result in absent or deficient antibody production that predisposes to recurrent or severe infections are discussed in detail. In these patients, IVIG is used as replacement therapy.

Agammaglobulinemia: Diseases with failure in B cell development or function may result in reduced or absent immunoglobulins, hypogammaglobulinemia, and agammaglobulinemia respectively. Primary agammaglobulinemia is most frequently an X-linked disease (Bruton's agammaglobulinemia), but several autosomal recessive forms also exist. These patients have an absence or nearly

absence of B cells, as well as tonsils and adenoids, and they present with recurrent bacterial infections of the respiratory tract. Agammaglobulinemia is the most classical indication for IgRT and it changed the clinical course and prognosis of the disease, reducing the frequency and severity of the infections (Perez et al., 2017; Ammann et al., 1982).

Severe combined immunodeficiency (SCID): These are a group of disorders that arise from a disturbance in the development and function of T and B cells, conferring a combined immune deficiency state. The term severe comes from the early death from overwhelming infections without treatment (Rivers and Gaspar, 2015). Typical SCID patients have absent or very low autologous CD3⁺ T cell count (<300/ μ L) and no or very low T cell function (phytohemagglutinin response <10% of the lower limit of normal), or the presence of circulating maternal T-cells. Leaky SCID patients have a reduced number of CD3⁺ T-cells with <30% of lower limit or normal T-cell function and absence of maternal engraftment. Patients with Omenn Syndrome have a generalized skin rash, absence of maternal engraftment detectable CD3⁺ T-cells, and absent or low T-cell function or oligoclonal T-cells (Sullivan and Richard Stiehm, 2020; Shearer et al., 2014). Patients with this group of diseases may have either an absence of B-cells or ineffective B-cell function since T-cell dysfunction hinders antibody production for humoral immunity. Initial management includes prevention of infection, antimicrobial prophylaxis, IRT, and avoidance of live vaccines (Bustamante Ogando et al., 2019).

Hypogammaglobulinemia and impaired antibody production: The prototype is common variable immune deficiency (CVID), a collection of hypogammaglobulinemia syndromes associated with poor or absent response to immunizations; one of the most frequently diagnosed IEI (Gathmann et al., 2014; Sullivan et al., 2014). IVIG reduces sinopulmonary infections; an early diagnosis and timely IRT is crucial to prevent chronic lung disease from chronic or subclinical lung infections (Busse et al., 2002; de Gracia et al., 2004; Lucas et al., 2010).

Class-switch recombination defects, also known as hyper-IgM syndromes, are another example of hypogammaglobulinemia with decreased IgG and IgA and normal or elevated IgM. The X-linked form (CD40L deficiency) and autosomal recessive CD40 deficiency result in a combined immune deficiency, beyond an antibody defect. With IRT there is a reduction of infectious complications (Winkelstein et al., 2003, 2006).

Selective antibody defects: In some cases, patients may have normal immunoglobulin levels, but an impairment of the production of specific antibodies, for instance, polysaccharide antigens. The response to polysaccharide antigens can be evaluated with measurement of antibody titers 4–8 weeks after vaccination with pneumococcal polysaccharide vaccine. A protective or adequate response to each serotype is a titer equal or greater than 1.3 μ g/mL, with at least a twofold increase in the titers. The number of pneumococcal serotypes that are protective after a vaccine can be used to define a normal antibody response, with >50% serotypes in children from 2 to 5 years and >70% in patients from 6 to 65 years. There is also a memory phenotype with an adequate initial response, but it wanes within 6 months. IRT should be provided when there is a well-documented polysaccharide non-responsiveness with evidence of recurrent bacterial infections (Orange et al., 2012a).

Isolated hypogammaglobulinemia: In transient hypogammaglobulinemia of infancy patients have transient low IgG levels that normalize with age and the antibody response is qualitatively normal. Select cases with recurrent bacterial infections may warrant IRT temporarily to decrease infections (Memmedova et al., 2013; Duse et al., 2010). Isolated hypogammaglobulinemia can also be a feature of many IEI and must be differentiated from secondary causes due to increased loss of IgG such as chylothorax, lymphangiectasia, enteropathy, massive proteinuria, and medications. An IgG level below 150 mg/dL is widely recognized as severe hypogammaglobulinemia and, upon confirmation of the low IgG value, IRT should be started promptly (Perez et al., 2017).

Normal immunoglobulin levels and other defects: Isolated subclass deficiency is often asymptomatic, but some patients might have associated poor specific antibody response and recurrent infections, and thus may benefit from IgRT (Abrahamian et al., 2010; Olinder-Nielsen et al., 2007). IgRT is not usually indicated for selective IgA deficiency, but in some patients, it may coexist with IgG2 subclass deficiency or poor specific antibody production. It is important to remember that IVIG can pose a risk for adverse reactions in IgA deficient patients with anti-IgA antibodies (Burks et al., 1986; de Albuquerque Campos et al., 2000), despite most patients receiving IVIG safely (Björkander et al., 1987; Rachid and Bonilla, 2012). IgA-depleted IVIG or subcutaneous route for immunoglobulin can be also considered (Perez et al., 2017).

Combined immunodeficiencies associated or with syndromic features frequently require IRT. Wiskott-Aldrich syndrome is an X-linked disorder associated with immunodeficiency, microthrombocytopenia, and eczema, as well as a predisposition for autoimmunity and malignancy. An impaired specific-antibody response is frequently seen, IRT reduces infection and should be considered (Ochs et al., 1980; Conley et al., 2003). Given the bleeding tendency in this disease, the subcutaneous route should be used cautiously. Ataxia-telangiectasia syndrome is also a genetic syndrome associated with immune deficiency, and over half the patients have both cellular and humoral impairment (Nowak-Węgrzyn et al., 2004). Other combined immunodeficiency phenotypes of IEI not discussed may also need IgRT.

Down syndrome is the most common genetic syndrome associated with immune defects, and some authors even consider it an inborn error of immunity (Huggard et al., 2020; Dieudonné et al., 2020). Multiple studies have demonstrated an immune dysfunction in patients with Down syndrome, including defects in the differentiation of B cells (Carsetti et al., 2015; Verstegen et al., 2014) as well as subclass imbalance and impaired vaccine response (Valentini et al., 2015; Nespoli et al., 1993; Ram et al., 2011). Routine vaccination of this group is imperative, and when recurrent bacterial infections continue to occur despite general measures, IgRT can be considered.

On some occasions, we might encounter a patient with recurrent bacterial infections with no yet characterized immune defect, IgRT can be an option for suspected IEI despite apparent normal humoral function. There are now over 400 IEI described, and indications of immunoglobulin therapy are an ever-expanding field (Tangye et al., 2020). In general patients with a clearly defined antibody production defect such as agammaglobulinemia, SCID, class-switch defect, or combined immune deficiencies, among

others, should be placed in IgRT as soon as the diagnosis is made. In other more specific antibody defects, the indication for replacement therapy should be based on the laboratory values, analyzed in the context of the patient's infection history, as well as preexisting comorbidities.

Treatment of secondary immune deficiencies

Secondary humoral impairment can result from several diseases or medications, increasing patients' vulnerability to bacterial infections. Secondary antibody deficiency (SAD) is more common than IEL and is being increasingly recognized (Patel et al., 2019). In secondary antibody deficiency, despite being more prevalent than IEL, clinical data on IgRT are limited (Na et al., 2019). Of note that in SAD there are important discrepancies among daily practice, clinical practice, guideline recommendations, and approved indications (Patel and Cowan, 2020; Agostini et al., 2016). Also, there is no consensus on the duration of IgRT in SAD, with 6 months to a year as the suggestion by some experts (Agostini et al., 2016).

Protein loss: The loss of great amounts of protein can also be an important mechanism for secondary hypogammaglobulinemia. Nephrotic syndrome, GI diseases, extensive dermatological alterations, lymphatic abnormalities (i.e., chylothorax, intestinal lymphangiectasia), and genetic syndromes can also result in hypogammaglobulinemia (Perez et al., 2017; Jolles et al., 2017). Procedures such as plasma exchange and chronic peritoneal dialysis can also result in hypogammaglobulinemia and may warrant IgRT (Lalan et al., 2017; Gupta et al., 2016).

B-cell lymphoproliferative diseases: In chronic lymphocytic leukemia (CLL) hypogammaglobulinemia is present in one-quarter of patients at diagnosis and up to two-thirds develop it in the course of the disease, it is an important predisposing factor for infection (Parikh et al., 2015; Wadhwa and Morrison, 2006). The use of IRT in CLL with high infection risk can effectively protect from bacterial infections (Cooperative Group for the Study of Immunoglobulin in Chronic Lymphocytic Leukemia et al., 1988). Patients with multiple myeloma (MM) are also at an increased risk for infection due to immune dysfunction and hypogammaglobulinemia (Backhaus et al., 2016); IRT has shown to lower incidence and recurrence of severe infections, particularly in MM patients with impaired vaccine response or more aggressive immunomodulatory regimens (Chapel et al., 1994; Khalafallah et al., 2010). Other malignant and hematological diseases such as lymphoma, leukemia, and myelodysplastic syndromes have also been associated with secondary hypogammaglobulinemia (Patel et al., 2019).

Hematopoietic stem cell transplantation (HSCT): Hypogammaglobulinemia is seen in up to two-thirds of patients post-HSCT and is higher in patients with acute graft vs host disease GVHD and patients receiving stem cells from an unrelated source (Frangoul et al., 2013). Currently, IgRT is not routinely recommended for all patients who undergo HSCT to prevent infection of GVHD (Raanan et al., 2008a; Cowan et al., 2015), a targeted approach to maintain normal IgG levels can be taken (Foster et al., 2018). Patients with recurrent bacterial infections and demonstrable antibody defects or chronic GVHD can benefit from IVIG therapy. Recipients of HSCT for an IEL with significant B-cell impairment that are receiving IgRT previous to the HSCT, like SCID, should continue it until humoral immunologic reconstitution (Perez et al., 2017).

Therapeutic agents: Drug-related antibody deficiency can account for one-fifth of all secondary antibody deficiency worldwide (Table 1) (Patel et al., 2019; Jolles et al., 2017; Compagno et al., 2014). High-dose and prolonged treatment with systemic corticosteroids can impair both cellular and humoral immunity (Wirsum et al., 2016). Mycophenolate mofetil (MMF) inhibits both T and B-cell proliferation and has also been shown to cause hypogammaglobulinemia (Kandyil et al., 2009; Boddana et al., 2011).

Rituximab, a chimeric IgG1 anti-CD20 monoclonal antibody, can cause hypogammaglobulinemia, which can be persistent and clinically significant (Casulo et al., 2013; Makatsori et al., 2014; Barmettler et al., 2018). Hypogammaglobulinemia can also be pre-existing, we strongly advocate pre-treatment evaluation with serum immunoglobulin levels, and if feasible, peripheral blood B-cells before rituximab therapy; since preexisting hypogammaglobulinemia is a risk factor for serious infections and sustained hypogammaglobulinemia (Compagno et al., 2014; Barmettler et al., 2018; Buch et al., 2011). The upsurge of new immunomodulatory and biologic therapies can be a harbinger for iatrogenic secondary deficiencies, a close surveillance should be maintained (Patel et al., 2019; Jolles et al., 2017).

Table 1 Therapeutic agents that may cause secondary antibody deficiency.

Corticosteroids
Mycophenolate
Antimetabolites and alkylating agents (i.e., cyclophosphamide)
Sulfasalazine and penicillamine
Tyrosine kinase inhibitors
Anti-epileptic medication
Anti-CD19 therapies (i.e., blinatumomab)
Anti-CD20 therapies (i.e., rituximab, ofatumumab, ocrelizumab)
Anti-CD22 therapies (i.e., epratuzumab, inotuzumab)
Anti-CD52 (i.e., alemtuzumab)
Anti-CD38 (i.e., daratumumab)
Anti-BAFF (i.e., belimumab)
Anti-FcRn (i.e., rozanolixizumab, efgartigimod)

Solid-organ transplantation: these patients receive immunosuppressive medications and undergo procedures that can cause hypogammaglobulinemia and carry an increased risk for infection; particularly after heart, lung, and kidney transplantation (Florescu et al., 2013; Madan et al., 2020). A combination of plasma exchange, immunoglobulin treatment, and/or B-cell depletion can be used for desensitization of highly sensitized patients to HLA or ABO group to improve transplant outcomes. A combination of these interventions has also been used for antibody-mediated rejection (Jordan et al., 2011). Patients with heart transplantation who receive pre-emptive replacement therapy may have fewer infections and episodes of rejection (Yamani et al., 2001). Patients should be closely monitored for hypogammaglobulinemia and they can also present with drug-resistant or severe viral infections that could benefit from immunoglobulin therapy (Florescu, 2014).

Pediatric HIV infection: HIV disease can lead to impaired antibody production, but hypogammaglobulinemia is uncommon (Opravil et al., 1991; Woudenberg et al., 2020; *New England Journal of Medicine*, 1995). Some trials from over 25 years ago found IVIG treatment to reduce bacterial infections and hospitalizations in HIV-infected children (Mofenson et al., 1994; Spector et al., 1994). With the advent of highly active antiretroviral treatment and antimicrobial prophylaxis, the advantage of IVIG in children with HIV is less clear (Huang et al., 2008).

Prematurity: newborn infants have an immature immune system and are highly dependent on transplacental transport of IgG, mainly in the third trimester; as such, preterm babies have a lower acquired IgG (van den Berg et al., 2011). Lower IgG levels in preterm infants are associated with an increased risk of infection, but prophylactic IgRT does not appear to modify clinical outcomes (Sandberg et al., 2000; Ohlsson and Lacy, 2020).

As discussed, many entities might lead to hypogammaglobulinemia and secondary antibody deficiency, this might lead to increased infection susceptibility. IgRT is generally reported to significantly reduce the rate of serious infections in patients with hematologic malignancies, but automatic prescription of IgRT is not recommended as no correlation has been established between IgRT and overall survival (Raanan et al., 2008b). The decision to start IgRT in secondary antibody deficiency should be individualized according to the degree of impairment of humoral immunity, the frequency, and severity of the infections, as well as the impact of general measures and prophylactic antibiotics (Perez et al., 2017; Na et al., 2019).

Immunomodulatory and anti-inflammatory therapy

Hematologic autoimmune diseases: Intravenous immunoglobulin is currently an effective and fast-acting first-line treatment for immune thrombocytopenia (ITP). Other first-line therapies include glucocorticoids and anti-D immune globulin; watchful waiting can also be considered. The choice of therapy is based on bleeding manifestations, the grade of thrombocytopenia, and risk factors, with IVIG achieving a faster platelet count increase (Beck et al., 2005; Rodeghiero and Ruggeri, 2014). IVIG is also a cornerstone in the treatment of neonatal alloimmune thrombocytopenia due to feto-maternal immunization and can be used as antenatal treatment (Massey et al., 1987; Rayment et al., 2011). In other autoimmune cytopenias, such as immune neutropenia or autoimmune hemolytic anemia, IVIG treatment can also be beneficial (Hilgartner and Bussel, 1987; Vagace et al., 2014).

Rheumatic diseases: Kawasaki disease (KD) is one of the most common forms of vasculitis in children and if left untreated up to one-quarter of patients can develop coronary artery aneurysms. The use of high-dose IVIG changed the course of KD significantly reducing coronary artery aneurysms (Oates-Whitehead et al., 2003; Furusho et al., 1983; Kobayashi et al., 2012). A single intravenous infusion of 2 g per kg of body weight is the recommended dose since it is more effective and equally safe than four smaller daily doses of 400 mg per kg of body weight (Newburger et al., 1991).

Multisystem inflammatory syndrome in children (MIS-C) is a complication of COVID-19 that can present not unlike KD in children. IVIG treatment is recommended for patients with MIS-C with KD characteristics (either complete or incomplete KD), as well as in patients with moderate to severe MIS-C without KD-like symptoms (Feldstein et al., 2020; Henderson et al., 2020; Whittaker et al., 2020).

Patients with autoimmune inflammatory myopathies; particularly dermatomyositis patients with severe weakness, resistant and recurrent disease can benefit from high-dose IVIG therapy (Cherin et al., 1994; Wang et al., 2012; Marie et al., 2010). In systemic lupus erythematosus (SLE) IVIG is associated with a transitory clinical improvement of disease activity and can be an additional aid for the treatment of patients with severe lupus multiorgan disease or patients with concurrent infections (Sakthiswary and D'Cruz, 2014; Zandman-Goddard et al., 2005).

IVIG can have a role in the management of systemic-onset juvenile idiopathic arthritis with an improvement of systemic features and is largely reserved for patients with unresponsiveness to standard therapy of macrophage activation syndrome. Macrophage activation syndrome may complicate systemic-onset juvenile arthritis, SLE, or KD (Uziel et al., 1996; Lin et al., 2012).

Other diseases in which IVIG treatment may be beneficial include systemic sclerosis/scleroderma (Young and Khanna, 2015), IgA vasculitis (Henoch-Schönlein purpura) (Mauro et al., 2019), polyarteritis nodosa (Asano et al., 2006), anti-neutrophil cytoplasm antibody (ANCA)-associated systemic vasculitis (Jayne et al., 2000), Takayasu arteritis (Velásquez et al., 2010), and autoimmune hepatitis (Vierling and Flores, 2002), among others. IVIG has also been proposed in a myriad of clinical conditions with an altered immune response such as blistering skin diseases (i.e., pemphigus) (Amagai et al., 2009; Czernik, 2014) and toxic epidermal necrolysis, and Stevens-Johnson syndrome (Seray et al., 2008; Huang et al., 2012; Roujeau and Bastuji-Garin, 2011; Zimmermann et al., 2017).

Neuroimmunologic disorders

Guillain-Barré syndrome (GBS) is a group of acute immune-mediated polyradiculopathies that most often presents as a monophasic paralyzing illness due to demyelination. Both IVIG and plasma exchange (PE) are effective treatments for GBS. IVIG effectiveness is considered comparable to plasma exchange but is more frequently used because of vascular access and tolerance to PE and is more likely to be completed (Hughes et al., 2014; Patwa et al., 2012).

Chronic inflammatory demyelinating polyneuropathy (CIDP) is a group of chronic neuropathies with immune-mediated demyelination characterized by a chronic relapsing-remitting course of motor-predominant neuropathy. Multiple randomized controlled trials have established IVIG and SCIG as effective treatments. Other treatment options include PE and glucocorticoids (Efthimov et al., 2013; Dyck et al., 1994; Gentile et al., 2020).

Multifocal motor neuropathy is characterized by progressive asymmetric weakness and atrophy without sensory alterations, it is treatable with intravenous IVIG, but is unresponsive to glucocorticoids or plasma exchange (Patwa et al., 2012; Cats et al., 2010). SCIG may also be beneficial in this disease (Racosta et al., 2017).

Myasthenia gravis is an autoimmune disorder of the postsynaptic neuromuscular union that presents with weakness. PE and IVIG are rapid-acting options useful in patients with severe or refractory disease; IVIG also has a short-term response in patients with non-severe exacerbations (Patwa et al., 2012; Gajdos et al., 2012; Barth et al., 2011). In *Lambert-Eaton myasthenic syndrome* there is a reduced acetylcholine release from the presynaptic nerve terminals and is strongly associated with small cell lung cancer as a paraneoplastic manifestation (Benatar et al., 2001), it can also present in patients with underlying immune-mediated diseases (Wirtz et al., 2004). IVIG has shown clinical improvement and is a second-line alternative in Lambert-Eaton myasthenic syndrome (Keogh et al., 2011; Bain et al., 1996).

Multiple sclerosis (MS) is a demyelinating inflammatory immune-mediated disease of the central nervous system. IVIG is a potentially effective second-line treatment in MS and is a fundamental alternative in patients during pregnancy or breastfeeding (Dudešek and Zettl, 2006; Sorensen et al., 2002).

Other neuroimmune diseases that may benefit from IVIG therapy include neuromyelitis optica spectrum disorder, acute disseminated encephalomyelitis, opsoclonus-myoclonus syndrome, Sydenham chorea, autoimmune encephalitis, pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection, and intractable childhood epilepsy (Patwa et al., 2012; Gadian et al., 2017; Wingerchuk, 2013).

Infection-related disorders

Sepsis and septic shock: IVIG has been used as adjuvant therapy for sepsis or septic shock reducing mortality in adults, and the use of IgM enriched formulations seems a promising therapeutic approach but remains experimental and further clinical data is needed (Alejandria et al., 2013; Jarczák et al., 2020).

Viral infections: In CMV pneumonitis high dose IVIG or high concentration polyclonal IVIG (CMV-IVIG) with ganciclovir combination has been reported to improve survival in patients post bone marrow transplant (Reed et al., 1988; Ljungman et al., 1992). Enteroviral meningoencephalitis can be a catastrophic complication in patients with agammaglobulinemia and is difficult to treat. Intensive high dose IVIG has been associated with clinical improvement and even long-term eradication. Intrathecal immunoglobulin may also be effective but adverse effects are common (Bearden et al., 2016; Alborizi et al., 2009; Misbah et al., 1992; Quartier et al., 2000). There may also be a clinical benefit of IVIG treatment for immunocompetent children with viral encephalitis, but not Japanese encephalitis (Iro et al., 2017). There have also been successful reports of IVIG in parvovirus B19 infection (Kerr et al., 2003; Cao et al., 2009; Katragadda et al., 2013). IVIG has also been used in persistent BK polyoma viremia and BK virus nephropathy in posttransplant patients (Vu et al., 2015; Kable et al., 2017). The usefulness of IGIV in viral myocarditis is still uncertain (Robinson et al., 2020).

Dosage of immunoglobulin

Different immunoglobulin doses can be administered based on the indication. In most IEI and secondary antibody defects a substitutive dose to prevent infections is used, when considering suppression of an inflammatory or autoimmune process higher doses are needed.

Immune deficiencies, either primary or secondary, might need a substitutive dose of immunoglobulin to achieve a passive immunity state.

Patients are usually started in a dose range of 400–600 mg per kg of body weight of IVIG per dose (Hernandez-Trujillo et al., 2012). Intravenous bolus doses can be administered every 21–28 days. In patients with severe hypogammaglobulinemia, a loading single dose of up to 1 g per kg can be given as the initial dose.

Subcutaneous preparations starting dose is usually 100–200 mg per kg of body weight per week and can be administered weekly or every 2 weeks. After subcutaneous infusion, the immunoglobulin is absorbed over several days and therapeutic plasma levels are not immediately achieved. Patients newly starting SCIG may receive a loading dose of IVIG 1 week before the initiation of SCIG (Ochs et al., 2006). A subcutaneous loading dose can also be administered as five consecutive daily doses or two doses per week for the first 2 weeks of the planned weekly dose (Borte et al., 2011; Koterba and Stein, 2015). To transition a patient from IVIG to SCIG one can divide the total monthly dose of IVIG and give it weekly with SCIG (Berger et al., 2011).

Hyaluronidase-facilitated SCIG allows higher volume per site and is usually given every 3 or 4 weeks, as with IVIG. The doses can be rounded up or down to the nearest presentation of the immunoglobulin product to not discard costly valuable medication (Perez et al., 2017; Jolles et al., 2015).

Dosing can be adjusted depending on the patient's clinical evolution and frequency of infections, the dose required may vary individually according to the patient's initial IgG levels, weight changes, renal or gastrointestinal losses, exposure to infectious diseases, and comorbidities (Shehata et al., 2010). Trough IgG levels can be measured before the next dose in patients with IVIG and random levels in subcutaneous administration. Some authors suggest achieving a specific IgG trough level or achieving near-normal IgG values, but some patients might even need trough levels above 800 mg/dL to prevent infections (Eijkhout et al., 2001; Quartier et al., 1999; Orange et al., 2010). Orange et al. analyzed studies evaluating trough IgG and pneumonia incidence in ICI with hypogammaglobulinemia receiving IVIG and conclude that pneumonia risk can be progressively reduced by higher trough IgG levels up to at least 1000 mg/dL (Orange et al., 2010). In a subsequent study, Orange et al. conclude that at higher SCIG doses and associated higher serum IgG levels clinical outcomes also improve (Orange et al., 2010, 2012b). The "biological through level" of IgG enough to prevent serious infections can vary for each patient, according to comorbidities and preexisting lung disease (Winkelstein et al., 2006; Bonagura et al., 2008). The dose of IVIG needed varies and the goal or IRT should be to improve clinical outcomes and not a specific number of IgG.

If a patient continues to present recurrent infections despite an adequate immunoglobulin dose, treatment adherence and other measurements (i.e., airway clearance therapy in bronchiectasis) should be examined before increasing the immunoglobulin dose. Some patients may experience a "wear-off" effect at the end of the dosing interval with IVIG like fatigue, myalgia, and arthralgia, which may represent subclinical infections (Rojavin et al., 2016). These patients may benefit from increasing the dose, shortening the interval infusion, or changing to a SCIG preparation.

In patients who require the immunomodulatory properties of IVIG higher doses from 1 to 2 g per kg of body weight are usually required. Patients with KD should receive a dose of 2 g per kg to decrease coronary aneurysms; and patients with GBS, multifocal motor neuropathy, and myasthenia gravis should also receive a total dose of 2 g per kg over 1–5 days, according to the specific pathology. In other indications as CIDP and autoimmune diseases, an initial dose of 1 g per kg can be used (Olivares et al., 2017; Espinosa-Rosales et al., 2018). In obese patients, the dose of SCIG/IVIG in immunodeficiency should be based on adjusted body weight and not actual body weight (Ameratunga, 2017).

The use of SCIG varies greatly between countries. SCIG does not require venous access and allows more flexible and convenient self-administration at home than IVIG. Pharmacokinetics may be preferable as SCIG leads to higher and more stable IgG trough levels (Table 2).

Adverse reactions of human immunoglobulin therapy

IVIG is generally considered a safe therapy. Most of the adverse reactions (AR) are mild and transient. The reported frequency of IVIG-associated adverse reactions ranges between 2% and 25% of all infusions, depending on the particular disease (García-Lloret et al., 2008). At replacement doses, the frequency is in the order of 10% or less. Because each IVIG product has unique safety and tolerability profiles, it is not uncommon to observe that patients who react to one IVIG product tolerate the infusion when switched to another brand (Orbach et al., 2005; Lin et al., 2011; Kapoor et al., 2020; Rachid et al., 2011; Rodríguez-Lozano et al., 2014). IVIG

Table 2 Pros and cons of immunoglobulin therapy routes of administration.

	<i>Pros</i>	<i>Cons</i>
IVIG	Administration every 3–4 weeks. Fast onset of action. More FDA-approved uses.	Health care facility administration. Requires intravenous access. More frequent systemic adverse effects. Peak and wear-off effect. Trough levels should be taken before the next dose.
SCIG	Home setting administration (Rapid-push or pump). No need of intravenous access. Useful in patients who do not tolerate an increase in intravascular volume. Cost-effective. Fewer systemic adverse effects. More consistent serum IgG levels. Trough values can be taken anytime.	Administration every 1–2 weeks. More frequent local adverse effects. Low volume per application site. May need multiple application sites per administration. Pain during administration.
fSCIG	Home setting administration. No need of intravenous access. Useful in patients who do not tolerate an increase in intravascular volume. Fewer systemic adverse effects.	Administration every 3–4 weeks. Two-step delivery system (hyaluronidase and immunoglobulin). Requires pump for administration. Small peak after infusion and lower levels of IgG before the next dose. Longer lasting local edema.

is a human blood-derived product and its administration carries the potential risk of transmission of infectious pathogens, however, no episodes of viral transmission caused by IVIG products have been reported after the institution of dedicated viral inactivation methods. AR are classified into immediate and delayed reactions and the frequency of their occurrence. Immediate AR include headache, flushing, fever, chills, myalgia, malaise, chest tightness, dyspnea, back pain, nausea, vomiting, diarrhea, blood pressure changes, and anaphylactic reactions, particularly in IgA-deficient patients. Late AR are rare and include acute renal failure, thromboembolic events, aseptic meningitis, neutropenia, autoimmune hemolytic anemia, skin reaction, and arthritis. Renal failure, usually transient, occurs mostly in the use of sucrose-containing products owing to osmotic injury (Orbach et al., 2005).

Less than 1% of subcutaneous infusions are systemic AR. Ochs et al. reported cephalalgia during or within 48 h following SCIG. SCIG's most common adverse effects are swelling, erythema, pain at the infusion site (Ochs et al., 2006). Extraordinarily, SCIG can also cause systemic anaphylactic reactions (Castano-Jaramillo et al., 2021). There are fewer cutaneous reactions with SCIG in secondary immunodeficiency patients compared with IEI patients.

Summary

Immunoglobulin administration revolutionized the treatment of IEI, particularly in preventing infections. IRT can be administered either subcutaneous or intravenously, each one with pros and cons. Multiple mechanisms of action have been proposed to be responsible for the efficacy of IRT, with anti-infectious and immunomodulatory effects. IgRT is effective and safe in the treatment of hypogammaglobulinemic patients.

Introduction

Immunosuppression is described as a condition of transient or permanent immune system deficiency arising from insults to the immune response with increased resistance to disease and the immune system. Such dysfunction also emerges from inflammation of the immune system cells, owing to their compromised activity in a non-specific manner against primary and subsequent pathogens (Schat and Skinner, 2014). Immunosuppression is the manifestation of the causative agent's overall replicative approach, leading to increased vulnerability to other pathogens, but not inherently to the causal factor (Venet and Monneret, 2018). The transplantation of human organs has advanced over the last 60 years and many people around the world have been saved. Preserving functionality of organs, one of the most important processes is transplantation. It involves Immunosuppressive medications or immunosuppressant widely used in patients to prevent organ rejection by exerting a suppressive effect on the immune system (Zhang and Zhang, 2018).

Immunosuppressant is a class of medicines that inhibit or decrease the intensity of the immune response in the body. Most of these medications, are used to allow the body less likely to resist a transplanted organ i.e., kidney, heart and liver. The most commonly and recent immunosuppressive drugs with their structures are shown in Fig. 1. Among these agents, the cortisol, cyclosporine-A, sirolimus, tacrolimus and mycophenolic acid immunosuppressive effect was discovered in 1949, 1976, 1977, 1987 and 1991, respectively (Sprague et al., 1950; Borel et al., 1994; Martel et al., 1977; Kino et al., 1987; Chapuis et al., 2000). Tacrolimus and cyclosporine-A belongs to calcineurin inhibitors, which mechanistically block the calcineurin effect by binding to immunophilins (Chakkerla et al., 2017). Similarly, Sirolimus is a Streptomyces hygroscopicus macrocyclic fermentation agent and a rapamycin mammalian target inhibitor (mTOR inhibitor), that inhibit the stimulation of T and B Cells by reducing interleukin-2 production. Sirolimus is extremely helpful in the prevention of kidney transplant rejection (Bellumkonda and Patel, 2020). In addition, the same inhibitory action is followed by everolimus—one of the tacrolimus derivative (Ashley et al., 2020). Inosine monophosphate dehydrogenase is involved in the synthesis of guanine monophosphate during purine synthesis. Mycophenolic acid reversibly inhibit Inosine monophosphate dehydrogenase, thus hitting a unique location during immunosuppression leads to the inhibition of T and B cells proliferation (Chitty, 2017).

In solid organ transplantation, immunosuppressive agents are needed for the activation of early-stage immunosuppression, the management of late-stage immunosuppression or for the maintenance of organ rejection (Pilch et al., 2021). Commonly used immunosuppressant agents are summarized in Table 1.

In addition to it, the site of action varies for various immunosuppressive agents as discussed earlier. For these agents the locus of action is briefly explained in Fig. 2. The emergence of novel agents and improvements in immunosuppression regimens after

Cyclosporine

Tacrolimus

Sirolimus

Everolimus

Mycophenolate mofetil

Fig. 1 Chemical structure of some commonly used immunosuppressive agents.

transplantation are significant factors leading to this progress (Nedredal et al., 2020). However, It also increases the risk of infection, cancers and specific adverse side effects specific to each agent in patients (Nogueira et al., 2018). Transplant centers across the world utilize multiple immunosuppression protocols; nevertheless, each patient can require an individually formulated immunosuppression regimen to manage the advantages and possible damage of treatment thus eliminating the likelihood of their primary disease recurrence (Gabardi et al., 2018).

This book chapter highlights a brief overview of immunosuppressive drugs along with its consequences in some special issues like corona virus disease, pregnancy and fertility.

Table 1 Commonly used immunosuppressant drugs in organ transplant.

ISDs	Class	Clinical indications	Recommended dose	References
Prednisone	Corticosteroids	Immunosuppression rejection, cellular rejection treatment	Variable to different locus	Broos et al. (2018)
Cyclosporine	Calcineurin inhibitor	Immunosuppression maintenance	10–15 mg/kg/day, every 12 h as a divided dose	Leclerc et al. (2020)
Tacrolimus	Calcineurin inhibitor	Immunosuppression maintenance	0.1–0.15 mg/kg/day every 12 h as a divided dose	Brunet et al. (2019)
Azathioprine	Anti-metabolite	Immunosuppression maintenance	1.5–2.5 mg/kg/day as a maintenance dose	Ford and Berg (2010)
Mycophenolate mofetil	Anti-metabolite	Rejection treatment, Immunosuppression maintenance	Varies in individual cases	Fareh et al. (2018)
Sirolimus	Mammalian target of rapamycin inhibitor	Malignancies, rejection treatment, immunosuppression maintenance	Oral: 6 mg followed by 2 mg/day as a single dose	Yap et al. (2018)
Everolimus	Mammalian target of rapamycin inhibitor	Malignancies, rejection treatment, immunosuppression maintenance	1 mg Bid	Rugo (2016)
Alemtuzumab	T-cell depleting monoclonal antibody	Immunosuppression induction	30 mg a single dose, or variable between centers	van der Zwan et al. (2018)

ISDs, Immunosuppressant drugs.

**Fig. 2** Immunosuppressant and their cellular site of action. Abbreviations; TAC, tacrolimus; CsA, cyclosporine-A; AZA, azathioprine; MMF, mycophenolate mofetil; IL-2, interleukin-2; TOR, target of rapamycin.

Immunosuppressive drugs

Immunosuppressive drugs or immunosuppressant are mainly categorized into four major classes' i.e., Glucocorticoids, Protein drugs, Intravenous gamma globulin and Protease inhibitor. Each class is further classified into subclasses. The detail is summarized in Fig. 3.

Glucocorticoids

Glucocorticoids are further divide into small molecule drugs that include immunophilins binding drugs like calcineurin inhibitors, cyclophilin binding drugs including cyclosporine, FK-12 binding drugs like tacrolimus, and TOR inhibitors like sirolimus and everolimus. In addition, another subclass of Glucocorticoids is nucleotide synthesis inhibitor that include Mycophenolate mofetil,

Fig. 3 Classification of immunosuppressive drugs.

mizoribine and mycophenolic acid (purine synthesis inhibitor). Another subclass include, inhibitor of pyrimidine synthesis, which include leflunomide, FK778, antimetabolites like Azathioprine and sphingosine -1- phosphate receptor antagonist (FTY720) (Stahn and Buttgeit, 2008).

Cyclosporine

Cyclosporine is an immune suppressive drug used in the treatment of immune diseases and transplant rejection. It is an isolated cyclic undecapeptide from *Tolypocladium inflatum*, exhibiting strong hydrophobic properties (Claro et al., 2018). Cyclosporine belongs to calcineurin inhibitor class (Kemmner et al., 2020).

Pharmacokinetics: Its oral bioavailability ranges from 30% to 90% (Lahiani-Skiba et al., 2018). Due to the lipophilic nature, it exhibit more than 95% affinity for binding with blood proteins (Sasano et al., 2017). Cyclosporine is metabolized in GIT, kidneys and liver by P450 3A enzyme, P glycoprotein and excreted in urine. The unchanged cyclosporine excretion ranges from 0% to 1%. The biliary route also take part in the excretion of metabolites for about 40% however exhibit lower toxicity as compared to parent compound (Minami et al., 2020). The half-life is 8–27 h, while it takes 1–2 h to achieve T_{max} .

Mode of action: Cyclosporine acts to inhibit immune responses which are mediated by cells. No effects on phagocytic activity in animals have been identified and bone marrow suppression in animal/human models is not induced. The cyclosporine mode of action is the inhibition of calcineurin, the inhibitor of cytochrome P450 3A4, and the inhibitor of P-glycoprotein. Cyclosporine-A inhibits the synthesis, of interleukins, which is necessary for the self-activation and differentiation of T lymphocytes. Cyclosporine is useful because immunocompetent lymphocytes in the G0 and G1 phases of the cell cycle are directly and reversibly blocked by it. Research has shown that cyclosporine inhibits CD4+ CD25+ Trigs, which may obstruct the ability for host immune tolerance (Liddicoat and Lavelle, 2019; Masi et al., 2019).

Indications: Cyclosporine is used clinically in solid organ transplantation for the prevention of organ rejection of allograft kidney, liver and heart transplants. It is indicated in patients with rheumatoid arthritis where the condition has not reacted sufficiently to methotrexate. The indications for psoriasis include the treatment of adult, non-immunocompromised, serious, intransigent, and plaque psoriasis patients who have not responded to at least one systemic treatment. Cyclosporine is approved to treat amyotrophic lateral sclerosis and its variants in patients with amyotrophic lateral sclerosis. Apart from it, the treatment of focal segmental glomerulosclerosis that does not react to corticosteroids is carried by cyclosporine during nephrotic syndrome. It stops and treats the disease in people with graft vs. host disease. Cyclosporine is recommended for refractory posterior uveitis and Behcet disease in the case of uveitis (Pradier et al., 2019; Tapia et al., 2020a; Ponticelli and Glassock, 2019; Xin et al., 2019; Sun et al., 2019).

Administration: An oral dose of 14–18 mg/kg is administered during 4–12 h pre transplant in adults. While in case of post-transplant, 5–15 mg/kg/day is administered twice a day in divided doses for 7–14 days. The dose is then reduced to 5%/week until it becomes 5–10 mg/kg/day twice a day in divided doses. The maximum concentration for intravenous administration of cyclosporine is 2.5 mg/dL. In case of 4–12 h pre-transplant, the intravenous dose is 5–6 mg/kg as a single dose for a period of 2–6 h. During post-transplant, after toleration of oral dose, the intravenous dose is 2–10 mg/kg/day. During Focal Segmental Glomerulosclerosis therapy, cyclosporine is administered 3 mg/kg/day orally every 12 h. In case of rheumatoid arthritis, starting oral dose is 2.5 mg/kg/day every 12 h. If the response is not effective after 8 weeks then a slight increment is carried out from 0.50 to 0.75 mg/kg/day, however, the maximum dose should not exceed than 4 mg/kg/day. Similarly, in case of psoriasis, starting oral dose is 2.5 mg/kg/day every 12 h. If the response is not effective after 4 weeks, then a slight increment is carried out up to 0.50 mg/kg/day, however, the maximum dose should not exceed than 4 mg/kg/day. Moreover, the dose is adjusted in each condition according to their trough level (Tapia et al., 2020b).

Adverse effects and contraindications: Cyclosporine has many adverse effects on multiple vital organs. It has adverse effects on cardiovascular system in the form of hypertension and arrhythmia. Due to an improved musculature of the glomerular afferent arterioles, cyclosporine reduces glomerular filtration rate. It raises serum creatinine concentration and reduces clearance of creatinine. The unwanted outcomes are associated with drug therapy length and dosage. The metabolic and endocrinological adverse effects of cyclosporine are hypertrichosis, hypomagnesaemia, hyperkalemia, dyslipidemia and gynecomastia. Convulsions, particularly in conjunction with high-dose methylprednisolone, encephalopathy, anxiety, headache, and fever, have been recorded as neurotoxic adverse effects of cyclosporine. Other general adverse effects include, mimicking risk of infection, level of TNF- α and chances of malignant lymphomas (Pal et al., 2019; Shin et al., 2019; Çamlar et al., 2018). Among drugs contraindicated to cyclosporine include, tacrolimus, simvastatin, amphotericin B, bosentan, lomitapide, oral neomycin, sitaxentan, cidofovir and pitavastatin. Other conditions include, asthma, active infections, attenuated vaccines, impaired renal function, BCG, uncontrolled hypertension, blood dyscrasias, ultraviolet radiations, coal tar, pregnancy and breast feeding (Boh et al., 2021; Ng et al., 2018).

Monitoring and toxicity: Therapeutic cyclosporine monitoring in transplant patients is a powerful method to reduce acute rejection, nephrotoxicity, and predictable dose-dependent adverse reactions by modifying the drug dosage. Within the living system an ideal therapeutic level of cyclosporine is maintained. In kidney transplant, after first week of transplantation a dose of 200–400 ng/mL is required followed by 125–175 ng/mL in the next week up to 6 months as a post-transplant dose. Then from 7th to 12th month of transplantation a dose of 100–150 ng/mL is monitored. After 1 year the final desired post-transplantation dose maintained is 75–160 ng/mL (Bertocchio et al., 2016). Similarly, in case of heart transplant, an ideal therapeutic dose of cyclosporine required is 250–350 ng/mL in the first 6 months accompanied by 100–200 ng/mL up to 12 months of transplantation. Same therapeutic level is maintained in case of liver transplantation (Jia et al., 2018). There is a very small spectrum of effective doses of cyclosporine and concentrations consistent with severe toxicity. Therapeutic failure or significant toxicity may result from sub-optimal doses or concentrations. Based on pharmacokinetics tests, cyclosporine is prone to therapeutic monitoring. The drug

variability range is from low to moderate level (Tafazoli et al., 2019). The establishment of a controlled airway is a priority in the event of toxicity. There is a need to check for signs of respiratory distress and, if necessary, provide breathing assistance. The healthcare provider still wants shock detection and treatment if necessary. They can expect and, if necessary, manage seizures and initiate positive and symptomatic counseling. The healthcare provider can withhold the medication for a few days or initiate alternative therapy until the patient returns to normal when over dosage occurs in patients administered cyclosporine therapy. It is mandatory to track serum levels of cyclosporine, and patients may require several dosage changes during the treatment process. For the injection of cyclosporine, the central venous catheter is not required and should be reliably used to obtain blood tests for serum cyclosporine levels. The treatment will be done directly after the infusion is stopped, provided the necessary 5 mL of blood using discard technique. Only 1% of dose is eliminated by hemodialysis (Alrashedi et al., 2018; Fan et al., 2019).

Tacrolimus

Tacrolimus is an immunosuppressive drug used for post-transplant organ rejection prophylaxis. The use of tacrolimus is associated with one or two other immunosuppressive drugs. For some autoimmune disorders, it has an application as an instrument for prevention or recovery.

Pharmacokinetics: Tacrolimus is metabolized by CYP3A4, 5 and P-glycoprotein, where the main metabolite produced is 13-O-dimethyl-tacrolimus along with other 15 chief breakdown metabolites. It has a half-life of 4–12 h with an average of 12 h. The volume of distribution for cyclosporine is approximately 30 L/kg with clearance of about 1.69 L/h/kg. About 95% of cyclosporine is excreted in bile while 2.4% in urine in unchanged form (Yu et al., 2018).

Mode of action: Tacrolimus belongs to calcineurin inhibitors, so it gets binds to FK506 binding proteins ultimately results in the inhibition of T-cells proliferation (Yoshikawa et al., 2020).

Indications: In stable organ transplantation, allogeneic transplants of the kidney, heart and liver tacrolimus act as the therapy of organ rejection. For the prevention of rejection in lung transplant patients, there is also an off-label indication. In addition, other off-label indications include myasthenia gravis, Crohn's disease, rheumatoid arthritis and graft versus host disease. Tacrolimus clinical uses also include topical application, as well as other off-label dermatologic disease states, in mild to extreme atopic dermatitis (Kalt, 2017). In comparison to traditional therapy, 0.05% topical tacrolimus improves vision acuity and decreases corneal irritation, neovascularization, and scarring in herpetic stromal keratitis (Akbari et al., 2019). Tacrolimus administration is favored up to 3 days before or within 10 days of post-nerve regeneration, experimental models have indicated in a research study (Saffari et al., 2019).

Administration: The administration of Tacrolimus can be oral, sublingual, topical, or intravenous. In immediate and extended-release formulations, oral tacrolimus is available. There are numerous pharmacokinetic parameters in the different formulations and they are not synonymous. Doses should be equilibrated for concentrations of desired target. To prevent post organ transplant rejection in adults, the initial oral dose in case of liver transplant is 0.1–0.15 mg/kg/day, which is administered as divide dose in the form of immediate release dosage form. In case of extended release dosage form the administered dose is 0.1–0.2 mg/kg/day one time most often in combination with corticosteroids. However, it should be noted that the extended release dosage form caused deaths in liver transplant patients in United States that's why it is not approved for use. The intravenous administration involves an initial dose of 0.03–0.05 mg/kg/day in the form of continuous infusion (Shamalin et al., 2017). Tacrolimus is administered in combination with antimetabolites for heart transplant. The initial oral dose is 0.075 mg/kg/day in the form of immediate release dosage form every 12 h in two divided doses. The initial intravenous dose is 0.01 mg/kg/day in the form of infusion (Han et al., 2019). In case of kidney transplant the tacrolimus is also used in combination with antimetabolites, where the initial oral dose in immediate release dosage form is 0.2 mg/kg/day with Azathioprine or the dose is reduced to 0.1 mg/kg/day with Mycophenolate mofetil. While the initial dose in case of extended release dosage form is 0.14 mg/kg/day and in combination with basiliximab is 0.2 mg/kg/day. The intravenous dose of tacrolimus is 0.03–0.05 mg/kg/day in infusion form, even so the intravenous route is not commonly applied due to severe nephrotoxicity (Dordal Culla et al., 2020; Taghvaye-Masoumi et al., 2020).

Adverse effects and contraindications: The adverse effects of tacrolimus include, hypertension, angina pectoris, abnormal dreams, insomnia, cardiac arrhythmias, tremors, headache, rash, acne, alopecia, pruritis, nausea, vomiting, diarrhea, urinary tract infections, abdominal pain, candidiasis, herpes simplex, muscle cramps, blurred vision, arthralgia, visual disturbances, tinnitus, otalgia, renal tubular necrosis, reduced serum iron, hyperlipidemia, hypomagnesaemia, weight gain and metabolic acidosis. Adverse effects of tacrolimus in the form of infection can be secondary to immunosuppression which emphasizes the importance of close control of the reduction of target doses to balance the likelihood of rejection (Fröhlich, 2019; Pham et al., 2011). Hypersensitivity and polyoxyl-60 hydrogenated castor oil are contraindicated to tacrolimus.

Monitoring and toxicity: Tacrolimus is a drug with a narrow therapeutic index. An important aid in the modification of opioid doses is the clinical control of tacrolimus in transplant patients. Although the use of tacrolimus is normally paired with other immunosuppressants, target levels generally decrease as post-transplant time increases to reduce nephrotoxicity and adverse effects induced by calcineurin inhibitor. Whole blood concentrations, usually taken around 30 min of the next dose, should be used. Therapeutic levels range from 5 to 20 µg/mL, but to reduce toxicity while reducing rejection, 5–15 µg/mL is sometimes used. Renal function, hepatic function, serum electrolytes, glucose, and blood pressure are additional monitoring parameters. Initially, thresholds should be assessed post-operatively 2–3 days a week, steadily declining as time progresses, reaching target thresholds, and stabilizing the patient. In case of pancreas/kidney transplant, the adult tacrolimus therapeutic level required is 8–12 ng/mL (<1 month), 6–9 ng/mL (1–3 months) and 4–8 ng/mL (>3 months). In case of liver transplant, the adult therapeutic level required

for tacrolimus is 6–9 ng/mL (<1 month), 4–8 ng/mL (1–3 months), 4–6 ng/mL (>3 months) and 3–5 ng/mL (>12 months). In case of heart transplant, the monitored dose is 9–12 ng/mL (<3 months), 8–9 ng/mL (3–6 months), 6–8 ng/mL (6–12 months) and 3–7 ng/mL (>12 months). In case of lung transplant, the therapeutic level of tacrolimus monitored is 10–12 ng/mL (0–3 months), 08–10 ng/mL (4–12 months) and 6–8 ng/mL (>12 months). Many drug-drug interactions occur due to tacrolimus' metabolism pathway. Additional surveillance is recommended before beginning drugs that impair or cause tacrolimus metabolism in order to avoid a supra/sub-therapeutic level (Nankivell et al., 2016; Andrews et al., 2017; Zwart et al., 2018). The toxicity of tacrolimus is typically acute renal failure. For patients on tacrolimus, close monitoring of serum creatinine, GFR, and urine production is important. Toxicity may also manifest as the production of detrimental symptoms such as tremors, disruptions of the electrolyte, headaches and elevated Serum creatinine (Jouve et al., 2019).

Sirolimus

Sirolimus is an immunosuppressive drug and mammalian target of rapamycin inhibitor.

Pharmacokinetic: Sirolimus is well absorbed after an oral dose administration of 2.5 mg and the $C_{\max}$ achieved is 41 $\mu\text{g/L}$. Its $t_{\max}$ is 3 h however dose dependent. It is hydrophobic in nature having extensive distribution exhibiting 6.9–19 L/kg steady state distribution volume. Sirolimus is portioned 95%, 3% and 1% to red blood cells, plasma and lymphocytes respectively. Sirolimus is metabolized by CYP2C8, CYP3A4, CYP3A5 and P-glycoprotein. Sirolimus exhibit variable metabolism in individuals, which is attributed to the expression variability of these enzymes. It has a terminal half-life of 63 h with clearance of 9 L/h. Liver is the main metabolism site for sirolimus and 92% metabolites are excreted in bile, while urine excrete only 1.2% metabolites (Moes et al., 2015).

Mode of action: Sirolimus inhibit Ca^{2+} based independent/dependent events during G1 phase of cell cycle after subsequent binding with FK506 and mTOR (FK506, tacrolimus binding protein; mTOR, mammalian target of rapamycin). Sirolimus also inhibit the release of interleukin and vascular endothelial growth factor (inflammatory mediators) from neutrophils. The differentiation and proliferation of T and B cells are inhibited by sirolimus through inhibition of cyclin dependent kinase (Vitiello et al., 2015; Zoncu et al., 2011).

Indications: Sirolimus in combination with corticosteroids is indicated for the transplant rejection in recipients with renal allograft. It is also used in the treatment of pulmonary lymphangioleiomyomatosis. In addition, sirolimus is used to treat skin cancer in recipients of kidney transplant as a secondary drug (Yoon et al., 2018; Mallat et al., 2017; Dantal et al., 2018).

Administration: In case of organ transplant rejection the oral loading dose for adults is 3 mg/m^2 on day first with weight less than 40 kg followed by a maintenance dose of 1 mg/m^2 once a day. While for recipients with body weight equal or more than 40 kg, the oral loading dose on day first is 6 mg/m^2 followed by an oral maintenance dose 2 mg/m^2 once a day. The loading dose in combination with corticosteroids for black transplant recipients—at high immunological risk, repeated transplant recipients and patients with reactive antibodies is 15 mg on first day of transplantation. The loading dose is followed by a maintenance dose of 5 mg/day administered on day second. Further dose of sirolimus can be adjusted based on trough level between days five and seven. The initial adult dose for pulmonary lymphangioleiomyomatosis is 2 mg/day. For the prophylaxis of organ transplant rejection the usual loading dose in pediatrics with body weight <40 kg and age greater or equal to 13 years is 3 mg/m^2 followed by a maintenance dose of 1 mg/m^2 once a day. While recipients with body weight greater than 40 kg, the oral loading dose is 6 mg/m^2 followed by an oral maintenance dose of 2 mg/m^2 (Ghasemi et al., 2020; El-Chemaly et al., 2017).

Adverse effects and contraindications: The main adverse effects of sirolimus include, acne, rashes, leucopenia, hyperlipidemia, diarrhea, hypokalemia, arthralgia, hypertension, hypercholesterolemia, nausea, vomiting, nasal congestion, blurred vision, stomach cramps, burning during urination, sore throat, dizziness, change in mental state, vaginal bleeding, irregular heartbeat and tremor. Hypersensitivity to drug, renal impairment, hepatic disturbances, hyperlipidemia and delayed graft function are the conditions contraindicated to sirolimus. The interacting drugs include mifepristone, ketoconazole, posaconazole, rifampin and diltiazem. The pregnancy category is C for sirolimus and it should not be administered to breast feeding mothers (Merkel et al., 2006; Chang et al., 2000).

Monitoring and toxicity: Blood levels of Sirolimus associate well with health outcomes and drug-related toxicity. AUC best represents the drug's true exposure, but if AUC tracking is superior to monitoring of troughs with respect to long term endpoints, is not fully investigated yet. The therapeutic level desired is 5–15 $\mu\text{g/mL}$ as a regimen for sirolimus, which should be monitored after transplantation. Sirolimus-treated patients often tend to be at increased risk for the development of infections with herpes simplex, particularly at the 5-mg dosage. However, with the use of this agent, the occurrence of fungal, bacterial or cytomegalovirus infections does not seem to be increasing. In addition, patients infected with sirolimus do not tend to be at elevated risk of developing proliferative diseases after transplantation within the first 6 months of transplantation (Adams et al., 2016).

Everolimus

Everolimus is an analog of the natural macrolide rapamycin and an immunosuppressive agent.

Pharmacokinetics: Everolimus is well absorbed after an oral dose administration of 2.5 mg and the $C_{\max}$ achieved is 45 $\mu\text{g/L}$. The absorption of everolimus is increased with administered concurrently with prednisone and cyclosporine with an average $t_{\max}$ of 2 h as compared to 1 h separate administration. The bioavailability is variable because it is substrate for metabolic enzymes and p-glycoprotein. The volume of distribution in a steady state is 111 L for a 70 kg recipient, which is increased by 1.3 L for each kg increase in body weight. Due to less hydrophobic nature about 75% is portioned into red blood cells and 25% gets bind to plasma

protein. Everolimus is metabolized by CYP2C8, CYP3A4/5 and P-glycoprotein. Liver is the main metabolism site for everolimus where 90% of its metabolites are excreted through bile and 1% in urine (Moes et al., 2012).

Mode of action: Everolimus has the same mechanism of action like sirolimus. It inhibits Ca^{2+} based independent/dependent events during G1 phase of cell cycle after subsequent binding with FK506 and mTOR (FK506, tacrolimus binding protein; mTOR, mammalian target of rapamycin). Sirolimus also inhibit the release of interleukin and vascular endothelial growth factor (inflammatory mediators) from neutrophils. The differentiation and proliferation of T and B cells are inhibited by sirolimus through inhibition of cyclin dependent kinase.

Indications: Everolimus is indicated for the renal, kidney and liver transplant. Carcinoma of the renal cells and breast cancer cells are also treated by everolimus. Apart from it, it is indicated for the tuberous sclerosis complex concerned with partial onset seizures and subependymal giant cell astrocytoma. In addition it is also indicated in the treatment of progressive pancreatic neuroendocrine tumors (Bilbao et al., 2015; French et al., 2016).

Administration and dosage: The initial oral dose administered for partial onset seizures associated with tuberous sclerosis complex is 5 mg/m^2 as a continuous dose until unacceptable toxicity or disease progression. While the oral dose for tuberous sclerosis complex associated with subependymal giant cell astrocytoma is 4.6 mg/m^2 once a day which is also continued until unacceptable toxicity or disease progression. Everolimus should be administered soon after kidney transplantation. The oral dose for kidney transplant rejection is 0.75 mg as a loading dose while the mentioned dose is adjusted until a trough level of 8 ng/mL is obtained. In case of liver transplant rejection the starting oral dose is 1 mg and maintenance dose is adjusted until a trough level of 5 ng/mL is achieved. Everolimus should not be administered at least 1 month of liver post-transplant because earlier administration may lead to loss of graft and even death (Saliba et al., 2011).

Side effects and contraindications: The side effects of everolimus include stomatitis, anemia, nausea, dyspnea, vomiting, constipation, pruritis, headache, fatigue, cough, hypertension, dry skin, pyrexia, epistaxis, asthenia and heart failure. Contraindications include hypersensitivity to everolimus. Concurrent administration of everolimus with ACE-inhibitors increases its side effects. Antidiabetic drugs lose its therapeutic effect upon administration with everolimus. Drugs which induces CYP3A4 reduces everolimus serum concentration while drugs which inhibit CYP3A4 increases everolimus serum concentration. Live vaccines are contraindicated with everolimus because immunosuppressants increase the adverse effects of live vaccines. A gap of at least 3 months should be kept between the administration of live vaccines and immunosuppressants (Casanovas et al., 2011; Pascual et al., 2017).

Monitoring: The therapeutic level of everolimus is 3–8 $\mu\text{g/L}$. The optimal trough level in a research study observed was 6–8 $\mu\text{g/L}$ with an AUC value of 120 $\mu\text{g h/L}$ (Moes et al., 2015).

Mycophenolate mofetil

Mycophenolic acid is an immunosuppressive drug used in the transplant rejection however due to its poor solubility its pro form i.e., Mycophenolate mofetil is used for enhanced oral absorption (Tönshoff et al., 2011).

Pharmacokinetics: Mycophenolate mofetil has a rapid absorption from small intestine and is not affected by food. The C_{max} in renal transplant recipients was 12 $\mu\text{g/mL}$ after 5 days of the transplant. Its volume of distribution is 3.5–4 L/kg. It mainly gets binds to albumin and plasma protein binding is 97%. When administered orally its apparent half-life is 18 and 17 h after i.v. administration. After intravenous dose the clearance is 178 and 192 mL/min after an oral dose. Mycophenolate mofetil is completely metabolized by liver carboxylesterase 1/2 into mycophenolic acid, the active parent compound, after both oral and intravenous administration. The enzyme glucuronyl transferase is then metabolized, creating MPA's inactive phenolic glucuronide. The escaped mycophenolate mofetil from metabolism in intestine reaches the liver via the portal vein and is converted into pharmacologically active MPA in the liver cells (Lamba et al., 2014). A limited fraction of drug is emitted into the urine as mycophenolic acid (<1%). In a pharmacokinetic analysis, when mycophenolate mofetil was administered orally, it was observed to be 93% excreted in urine and 6% in feces. Around 87% of the entire dosage given is observed to be excreted as an inactive metabolite, MPAG, in the urine (Villarreal et al., 2009).

Mode of action: T-cell and B-cell proliferation and the development of cytotoxic T-cells and antibodies are inhibited by the active metabolite of mycophenolate, mycophenolic acid. Adhesion of lymphocytes and monocytes to blood vessel endothelial cells that are usually part of inflammation is avoided by MPA glycosylation of cell adhesion molecules. It also inhibit Inosine monophosphate dehydrogenase reversibly and selectively, thus without involvement in the DNA it blocks the denovo guanosine nucleotide pathway. Because the proliferation of B and T cells depend upon denovo purine synthesis (Park, 2011; Sagcal-Gironella et al., 2011).

Indications: It is indicated in heart, renal and liver transplant. It is also indicated in steroid resistant nephrotic syndrome. In addition to it, Mycophenolate mofetil is indicated in rheumatology and autoimmune hepatitis (Broen and van Laar, 2020; Roberts et al., 2018).

Administration and dosage: In case of organ transplant, it is given orally in combination with tacrolimus or cyclosporine in a dose of 600 mg/m^2 bis a day. After transplant, the first dose should be administered within 72 h, whereas the maximum dose should not be exceeded than 2 g per day (Kim et al., 2018).

Side effects and contraindications: Main side effects include hypoglycemia, leucopenia, back pain, fever, opportunistic fever, headache, sepsis, necrosis, hypertension, hypo chromic anemia, bleeding, vomiting, nausea, acne, melanoma and tremors (Kaltenborn and Schrem, 2013). Mycophenolate mofetil is contraindicated in patients with known hypersensitivity to it. Mycophenolate mofetil exposed recipients are at a higher risk of malignancies and lymphomas, especially of skin. The concerned patients

should avoid sunlight and the drug is contraindicated in gastrointestinal patients. The drug should be taken on empty stomach and concurrent use of multivalent ion is contraindicated (Dias-Polak et al., 2019).

Toxicity: The oral LD50 of Mycophenolate mofetil in rat is 250 mg/kg while greater than 4000 mg/kg in mice.

Mizoribine

Mizoribine is an immunosuppressive and imidazole nucleoside agent. As compared to Azathioprine, it exhibits minimal toxicity and thus used as an alternative in immunosuppression.

Pharmacokinetics: Mizoribine is widely agreed to be readily ingested from the digestive tract and excreted into urine as an unchanged form in stable human subjects at a rate of 65–100% of the dosage. Mizoribine disposal from the circulatory system is strongly dependent on renal activity. However, marked inter-individual heterogeneity in the oral bioavailability of mizoribine, where the oral bioavailability of mizoribine ranged from 12% to 81% of the dose in recipients of kidney transplants, is also noted. It has a half-life of 3 h, metabolized by liver and excreted in urine (85%) and bile (1%) (Murakami and Mori, 2012).

Mode of action: Mizoribine during S phase of cell cycle inhibits the DNA synthesis leading to its immunosuppressive action. It has a very unique mode of action on lymphocyte that prevents its proliferation in other cell types without interfering with purine synthesis. The de novo and salvage pathways are mainly responsible for purine synthesis. The ribose phosphate portion of purine nucleotides in the de novo pathway is derived from 5-phosphoribosyl 1-pyrophosphate, which is extracted from ATP and 5-phosphate ribose, and the lymphocytes rely primarily on the de novo pathway. Purine bases, sugars and other materials are effectively processed through the salvage pathway, and most cells are able to use the salvage pathway, including polymorphonuclear leukocytes and neurons. Mizoribine specifically inhibits the de novo pathway so consequently inhibits proliferation of lymphocytes (Liu et al., 2018; Wang et al., 2016).

Indications: Mizoribine is indicated for the renal transplantation. It has an immunosuppressive effect similar to Azathioprine, however with less adverse effects. IgA nephropathy is a condition characterized by histological deposition of IgA and characterized by proteinuria and microhematuria clinically. Mizoribine in combination with corticosteroids reduces the production of IgA leads to the inhibition of abnormal immune response. Mizoribine can also be used in patients with nephrotic syndrome exhibiting steroid resistance. For the treatment of steroid-dependent pediatric patients with lupus nephritis, high-dose mizoribine therapy has demonstrated adequate effectiveness and protection to justify its use. In addition, mizoribine can also be indicated in the treatment of renal vasculitis, rheumatoid arthritis and glomerulosclerosis (Kawasaki, 2009; Shiraishi et al., 2018).

Administration: The initial oral dose of mizoribine in organ transplant is 6 mg/kg/d followed by a maintenance dose of 10 mg/kg/day (Ushigome et al., 2016). The oral adult dose in nephrotic syndrome is 50 mg three times a day. For rheumatoid arthritis the oral dose is also 50 mg three times a day. While its immunosuppressive dose in renal transplant patients is 1–3 mg/kg/day.

Side effects and contraindications: A total of 4906 cases seeking mizoribine treatment for kidney transplantation and three disease patients were involved in different kinds of clinical trials and a post marketing monitoring review. Leucopenia, impaired hepatic activity, rash, elevated uric acid levels, hyperuricemia and vomiting were the major adverse reactions associated with the use of mizoribine. Hypersensitivity to mizoribine is its main contraindication. The concurrent administration of mizoribine with bezafibrate increases the risk of rhabdomyolysis (Shi et al., 2017; Akioka et al., 2017).

Monitoring: In order to ensure that the plasma drug dosage is within the therapeutic range, doses must be checked periodically in renal patients. During care, monitor serum uric acid daily, increased risk of malignancy and infections, cautious use in patients with active GI tract disorders. Live vaccines can be stopped as well.

Leflunomide

Leflunomide is a disease modifying antirheumatic drug and pyridine synthesis agent that exhibits immunosuppressive effect. It has heterogeneous both pharmacologically and chemically (Jaw et al., 2017).

Pharmacokinetics: Leflunomide is well absorbed after oral administration. After dosing the peak plasma concentration is achieved in 6–12 h. It has a short half-life of 2 weeks, volume of distribution is 0.12 L/kg and plasma protein binding is greater than 99%. Leflunomide follows hepatic metabolism and after oral administration it is converted into its active form. Via further metabolism and eventual renal excretion, as well as direct biliary excretion, the active metabolite is removed. About 43% of the overall radioactivity was removed in the urine and 48% was eliminated in the stool in a 28 day drug removal trial using a single dose of radio labeled compound (Bergner et al., 2013).

Mode of action: Following oral administration, the pro drug leflunomide is converted into its active metabolite (A77 726), which is responsible for the in vivo activity of the drug. Leflunomide mode of action has not been entirely determined, but seems to mainly involve autoimmune lymphocyte control. It has been proposed that leflunomide confers its immunomodulatory effects by limiting the transmission of stimulated autoimmune lymphocytes by cell cycle progression intervention. In vitro results show that leflunomide interacts with the progression of the cell cycle by inhibiting dihydroorotate dehydrogenase, a mitochondrial enzyme involved in the synthesis of de novo pyrimidine ribonucleotide uridine monophosphate, which has antiproliferative activity (Alcorn et al., 2009).

Indications: To improve physical activity and to delay the progression of neurological deterioration associated with the condition, for the treatment of the signs and symptoms of active rheumatoid arthritis (RA). Leflunomide has since been used in solid organ transplant recipients to avoid acute and chronic rejection, and is approved by the FDA as an orphan drug for such use. During lung transplant, it is indicated for the cytomegalovirus infection (Silva et al., 2018).

Administration: The loading dose over 18 years and adults is 100 mg/day for 3 days.

Adverse effects and contraindications: Main adverse effects include alopecia, back pain, headache, bronchitis, abdominal pain, hypertension, nausea, dyspepsia, infection, rashes, weight loss, vomiting, stomatitis, cough, chest pain, rhinitis, eczema, sinusitis and dry skin. Severe hepatic impairment, hypersensitivity, pregnancy and teriflunomide are the contraindicated conditions for leflunomide (Boyd, 2012; Singer and Gibofsky, 2011).

Toxicity: The LD50 value ranges from 100 to 250 mg/kg.

Azathioprine

Azathioprine is a 6-mercaptopurine pro drug used in immunosuppression.

Pharmacokinetics: Azathioprine is well absorbed after oral administration and it takes 1–2 h as its maximum time. It has a distribution volume of 1.75 L/kg with half-life of 41 min (Colombel et al., 2019). Azathioprine exhibits 30% albumin binding capability. Non-enzymatically Azathioprine is transformed into 6-mercaptopurine which in turn through the action of thiopurine methyltransferase is converted to 6-methyl mercaptopurine (6MP). 6-MP is converted to either the inactive 6-methylthiopurine nucleotide (6-MMP) or 6-thiourea acid (6-TA). (2) 6-MP is converted to active metabolites known as 6-thioguanine nucleotides under the action of hypoxanthine phosphoribosyl transferase, Inosine monophosphate dehydrogenase and guanosine monophosphate synthase. Its metabolites are excreted in urine (Lin et al., 2021).

Mode of action: Azathioprine inhibits T and B cells proliferation (Alhabbab et al., 2019).

Indications: Azathioprine is clinically indicated to prevent transplant rejection of heart, liver and urinary system. It is also indicated in the treatment of vasculitis, connective tissue and inflammatory bowel disorders. Apart from it, Azathioprine is indicated in lupus nephritis, myasthenia gravis, autoimmune hepatitis, rheumatoid arthritis and juvenile idiopathic arthritis (Horneff, 2015; Björnsson et al., 2017; Sanders et al., 2015; Shah and Verma, 2016; Montante et al., 2019).

Administration: To prevent organ transplant rejection, the initial oral/intravenous dose is 3–5 mg/kg/day at least 3 days before organ transplant followed by maintenance dose of 1–3 mg/kg/day via both route of administration. The oral dose in case of lupus nephritis is 2 mg/kg once a day either alone or in combination with corticosteroids. However, corticosteroids should be administered in lower doses. In case of inflammatory bowel diseases and idiopathic arthritis the initial oral or intravenous dose is 1 mg/kg/day either single/divided dose (12 hourly), with a slight increment in dose of 0.5 mg/kg/day after 6–8 week of transplant and then the same dose is maintained every month. The maximum dose should not exceed than 2.5 mg/kg/day (Mohammadi and Kassim, 2019).

Adverse effects and contraindications: Main adverse effects of Azathioprine include dizziness, vomiting, bone marrow suppression (reversible), diarrhea, rashes, lymphoma, fever and pancreatitis. Patients with known hypersensitivity to Azathioprine should be avoided to use it. Azathioprine is contraindicated with drugs like chlorambucil, melphalan and cyclophosphamide. Azathioprine administered to patients treated with those drugs has a greater chance of neoplasia. Azathioprine and allopurinol has a close interaction, the dose of Azathioprine must be reduced during its concomitant administration with allopurinol. Live vaccines concomitant administration with Azathioprine is contraindicated (Fuggle et al., 2015; Ahmed et al., 2016).

Toxicity: In case of Azathioprine overdose the recipients experience bleeding, infections and bone marrow depression that may lead to death. A 45% dose is removed from serum through hemodialysis however supportive and symptomatic treatment should be carried out in case of toxicity (Ghalamkari et al., 2019).

Protein drugs

Alemtuzumab

Alemtuzumab is a humanized monoclonal antibody having specificity to lymphocyte antigens. Basically it is a recombinant DNA-derived humanized monoclonal antibody (Campath-1H) which is focused against the 21–28 kD cell surface glycoprotein, CD52.

Alemtuzumab after intravenous administration it has a bioavailability of 100%. While for subcutaneous administration the observed bioavailability was 47%. It has been reported that C_{max} of 3014 ng/mL on day 5 after administration of 12 mg/day for 5 consecutive days via IV route. Where a mean C_{max} of 10,700 ng/mL was observed in patient with chronic Lymphocytic leukemia administration of 30 mg of alemtuzumab thrice a week for 8 weeks. In case of subcutaneous administration C_{max} can be achieved within 48 h (Hale et al., 2004). Alemtuzumab is likely to distribute between plasma and interstitial space as it is not expected that it may cross the cell membrane due to its size. The reported volume of distribution in patient with multiple sclerosis is 14.1 L and 11.3 L in patient with chronic Lymphocytic leukemia. The soluble form of CD52 may bind to alemtuzumab resulting in reduction of free and bioactive drug concentration. No data is available for binding of alemtuzumab with other protein (Berger et al., 2017). The plasma half-life of alemtuzumab is 6.1 days in patient with chronic Lymphocytic leukemia, 8–21 days in patient of stem cell transplant recipient and 4–5 days in patient with relapsing-remitting multiple sclerosis (Berger et al., 2017). The clearance mechanism of alemtuzumab is not well understood. The likely metabolic pathway is degradation of alemtuzumab into small peptides and distinct amino acids by proteolytic enzymes (Berger et al., 2017). Alemtuzumab shows its action by selectively inhibiting the CD52 which is a protein present on the surface of B and T lymphocyte in high level and at lower level on the surface of natural killer and other cells type involved in inborn immunity. The inflammatory diseases activity is reduced due to depletion of T and B lymphocyte (Berger et al., 2017). A solution for IV or SC administration is available in 30 mg/1 mL vial or 12 mg/10 mL vial. The dose of alemtuzumab is dependent on indication. In patient having relapsing-remitting multiple sclerosis alemtuzumab is administered in a dose of 12 mg/day for 5 days followed by a dose of 12 mg/day for 3 days at 12 months. In patient having chronic

lymphocytic leukemia the starting dose is 3 mg IV followed by a second and third dose of 10 mg and 30 mg. Afterwards, 30 mg/kg is recommended thrice a week for maximum up to 12 weeks. In solid organ transplant 1 or 2 doses of 30 mg alemtuzumab are administered (Marsh et al., 2016; Clatworthy et al., 2007). No specific data is available on the toxicity of alemtuzumab.

Muromonab

Muromonab-CD3 a monoclonal antibody, is immune-suppressing agent used to reduce rejection in patient undergoing organ transplant (Midtvedt et al., 2003). It is cleared predominantly by binding to T lymphocytes. It has 100% bioavailability after IV administration. The volume distribution, distribution characteristics and binding is not fully elucidated. There are two phases of Muromonab removal after IV administration. The initial quick removal phase which may be credited to binding with T lymphocyte and clearance by reticuloendothelial system. The second phase of clearance is a slow phase and occurs within 6–10 days. The half-life is approximately 18 h (Morrison, 1985; Boulianne et al., 1984). It is indicated in renal, liver and heart transplant. It is also used in T cells acute lymphoblastic leukemia (Gramatzki et al., 1995). Muromonab shows its action by to T cell receptor CD3 complex and induces TCR complex clearance from cell surface and apoptosis of T cells and ultimately provide protection to transplant against T cells (Woo and Robinson, 2015). It is administered in a dose of 5 mg through IV push every day for 10–14 days (Hooks et al., 1991). Cytokine release syndrome is produced during first infusion which results in side effect like headache, nausea, fever, fatigue, myalgia and may lead to life threatening situation i.e., apnea, flash pulmonary edema and cardiac arrest. Leucopenia and neurological side effects (encephalopathy and aseptic meningitis) have also been observed. Tachyphylaxis has been reported in case of repeated administration (Bhorade and Stern, 2009; Abramowicz et al., 1989). The drug is contraindicated in condition like heart failure, epilepsy, allergy pregnancy and uncontrolled arterial hypertension (Woo and Robinson, 2015).

Therapeutic monitoring is required to evaluate the cause for failure response during and after the course of therapy. The Probable etiologies for failures comprise immune clearance as a result of production of human antimouse antibodies, an unusually extraordinary clearance rate of the mouse immunoglobulin. The strategies for therapeutic monitoring comprise determining the fraction and total marginal lymphocyte subclass populations i.e., CD-2,3,4 and 8, level of drug, and human antimouse antibodies production. T lymphocyte and anti-muromonab antibodies detection are used for the monitoring of Muromonab CD3. T lymphocyte become disappear after the initial injection. However, a major number of cells reappear after several days of treatment but they do not express CD3 molecule rather presents CD 4 and 8 molecules. The first indication of ineffective response is the reappearance of CD 3 positive T lymphocytes (Colvin et al., 1983).

Rituximab

Rituximab is basically a hereditarily contrived chimeric mouse/human IgG1-kappa monoclonal immunoglobulin having murine heavy and light chain flexible area orders and human constant area orders. Its molecular weight is roughly 145 kDa and contained 2 hefty chains of 451 amino acids and 2 light chains of 213 amino acids (Tandan et al., 2017). A concentration of 157 µg/mL is achieved after first administered dose. It has a volume of distribution of 3.1 and 4.5 L in patient having rheumatoid arthritis and granulomatosis, respectively. Mostly it is metabolized and cleared from the body via reticuloendothelial system. It has a half-life of 22, 18, and 21 days in non-Hodgkin lymphoma, rheumatoid arthritis and chronic -lymphocytic leukemia, respectively. Rituximab shows its action by binding to CD 20 surface cell protein, which play a role in calcium influx and allow activation of B cells. It binds crosswise, on the side where cap is formed by CD20 and drawing protein over that side. Due to the presence of cap, the effectiveness of natural killer cell is enhanced for destroying B cells (Rudnicka et al., 2013). Rituximab is used to treat autoimmune disease and certain cancer types. It is indicated in chronic lymphocytic leukemia, non-Hodgkin lymphoma, myasthenia gravis, rheumatoid arthritis, mucocutaneous ulcer and granulomatosis with polyangiitis (Azrieh et al., 2020). It is administered in a dose of 375 mg/m² IV once a week (total of 4–8 doses) in relapsed or refractory low-grade CD20 positive patients. In chronic lymphocytic leukemia the dose is 375 mg/m² on day one of 1st cycle and 500 mg IV on day first of 2–6 cycle of chemotherapy. In case of rheumatoid arthritis, a dose of 1000 mg is administered via infusion and repeated after 2 weeks. The course is repeated every 24 weeks. Adverse events include infusion reaction, acute kidney injury, cardiac arrest, tumor lysis syndrome, pulmonary toxicity, hepatitis B and other viral infection, perforation and bowel obstruction (Ollier et al., 2009). The toxicity values are, oral LD50 is 27 mg/kg for both mice and rats, 32 mg/m³ in mice and 37 mg/m³ in rats via inhalational route.

Belatacept

Belatacept, is a fusion protein comprised of the Fc portion of human IgG1 immunoglobulin allied to the extracellular dominion of CTLA-4 (a molecule crucial in the regulation of T cell co-stimulation, selectively blocking the process of T-cell activation). It was approved by FDA on June 15, 2011 (Vincenti et al., 2016). A C_{max} value of 247 and 139 µg/mL are achieved after initial 10 mg/kg and maintenance dose of 5 mg/kg. the volume of distribution is 0.11 L/kg with the dose 10 mg/kg. The drug is metabolized to amino-acids and smaller peptide by proteolytic enzyme. Half-life is 9.8 days. Normally 0.49 mL/h/kg of drug is cleared from the body. It shows its action by binding specifically to CD80 and 86 receptors of the antigen presenting cells and the T cell will not be able to response to their antigen. It is administered in initial dose of 10 mg/kg on day of transplant, the dose is repeated on day 5 and at the end of weeks 2, 4, 8, and 12. A maintenance dose of 5 mg/kg at the end of week 16 after transplantation which is repeated every 4 weeks. The adverse events include anemia, diarrhea, UTIs, hypertension, cough, headache, abdominal pain, insomnia and graft dysfunction. No specific data is available on Belatacept toxicity (Vincenti et al., 2016; Wekerle and Grinyó, 2012; Garnock-Jones, 2012).

Immunosuppressive drugs in some special cases

Fertility and pregnancy

In most cases, especially after the first year of allogeneic organ transplantation, immunosuppression severity decreases with time. The eradication of diseased cells by chemotherapy is often followed by allogeneic hematopoietic stem-cell transplantation. There is a dose-dependent reduction in testosterone plasma concentrations, a rise in gonadotrophins and an improvement in spermatogenesis relative to the values of the general population in transplanted male patients. However, these gonadal changes before organ transplantation are less considerable (Xu et al., 2011). The usefulness of immunosuppressive medicinal products in the treatment of various diseases along with the advent of novel medicinal and better knowledge of their side effects has indicated immunosuppressants in pregnancy. Since these drugs were contraindicated several years ago mainly due to their teratogenic effects. Similarly, steroids is implicated in an increased risk of premature disruption of the membrane and cyclosporine in increased premature birth rates, although the increased risk of premature birth in female transplant recipients is often attributed to maternal status and not to immunosuppression. However, immunosuppressive agents, notably steroids and tacrolimus, are exacerbated by the risk of gestational diabetes and hypertension. Creatininemia greater than 12 mg/L before birth and the use of anticalcineurin is often an elevated risk of pre-eclampsia. The probability of fetal hepatitis C virus's transmission is about 4.9% and depends on the viral load of the mother in post liver transplantation (Westbrook et al., 2015). Eventually, breastfeeding should be taken into consideration because of passage of possible harmful metabolites into the milk and thus to neonates (Constantinescu et al., 2014).

Concerning the deleterious influence of methotrexate on spermatogenesis, the research findings vary. If it is true, this effect tends to be reversible after 3 months of discontinuation of treatment. Men are recommended to wait 3 months after halting therapy to conceive because of the mutagenic effect. No evidence of a teratogenic effect is available (Grosen et al., 2017). No evidence on the impact of Mycophenolate on male fertility is available. A similar incidence of prematurity and malformations was associated with many births involving transplanted fathers who were treated with Mycophenolate, as seen in the general population (Morken et al., 2015). Cyclophosphamide is mutagenic, teratogenic and lethal to embryo in mammals. In humans, it promotes extremity and head malformation so it is confirmed teratogenic agent.

Corona virus disease

In order to inhibit and manage the hyper inflammatory process of COVID-19, it is speculated that immunosuppressive medications may be used. These medications, however, also suppress the host immune response to the virus. Thus, in earlier phases of COVID-19, they may be dangerous. The net impact of immunosuppressive medications in COVID-19 patients is undergoing significant debates. Corticosteroids have a broad variety of anti-inflammatory and immunomodulatory properties, including suppression of pro-inflammatory cytokine production, reduction of the trafficking of leukocytes and activation of T-lymphocyte apoptosis (Lansbury et al., 2019). Five retrospective studies showed that there was no gap in SARS-CoV-2 clearance time among patients treated and untreated with steroids (Fang et al., 2020). Three other clinical trials, on the other hand, confirm that steroid therapy was associated with a longer period of time before SARS-CoV-2 clearance. In both these studies, the probability of misunderstanding was high (Xu et al., 2020). An alteration in host cells triggered by viruses that leads to cell death is known as cytopathic effect. A number of in vitro experiments have shown that cyclosporine greatly inhibits SARS-CoV and MERS-CoV viral replication and cytopathic effects in infected cells in a dose-dependent manner (Sauerhering et al., 2020). Similarly, another in vitro study showed that in VeroE6/TMPRSS2 cells, mycophenolic acid inhibits SARS-CoV-2 replication. Human pluripotent stem cells were differentiated into lung organoids in another study and were then contaminated with SARS-CoV-2. Mycophenolic acid blocked viral replication in these lung organoids, while SARS-CoV-2 cytopathic effect was still detected, but with high levels of mycophenolic acid (Sauerhering et al., 2020; Han et al., 2020). Yet another retrospective cohort analysis showed that a higher mortality risk and incidence of bacterial infection were correlated with the treatment of COVID-19 patients with tocilizumab. Patients infected with tocilizumab were, however, more chronically sick than the controls. They were both much older and administered antiviral and glucocorticoids more often than the controls (Quartuccio et al., 2020).

The findings of some clinical trials indicate that in patients with COVID-19, corticosteroids are helpful, particularly in the prevention of cytokine storm effects. A lower mortality rate (28-days), a shorter hospital stay and a lower incidence of mechanical ventilation were linked with the use of dexamethasone (Horby et al., 2020). Dexamethasone did not impact death rates in patients that did not need oxygen assistance. The implications of these studies reinforce the theory that the hyper inflammatory process of COVID-19 may be avoided and treated by using immunosuppressive drugs.

Conclusion

In the 21st century, because of their effectiveness, but also because of a greater understanding of their modes of action and their side effects, immunosuppressive medications are indicated in several various diseases. This effectiveness has made it easier to improve underlying illnesses, making parenthood an alternative in certain young patients who've had definitive life-threatening disorders before. These procedures, however, remain effective therapies that involve skillful handling; it should also be borne in mind that the long-term effects are still not well understood. Recommendations for use of a very low standard of evidence are drawn up, and must

be taken into consideration when advising and tracking patients. In the treatment of COVID-19, certain immunosuppressive medications may be beneficial. Mycophenolic acid prevents in vitro SARS-CoV-2 replication. There are signs that some immunosuppressive agents in patients with COVID-19 can reduce mortality and avoid mechanical ventilation. In high-quality clinical trials, these findings have to be checked before these medications can be adopted as routine treatment. Focused on the promising findings of other immunosuppressive agents in SARS-CoV and MERS-CoV in vitro trials, it would be useful to examine their effects on the replication of SARS-CoV-2. Close observation of pregnancy in accordance with the immunosuppression prescriber and long-term check with these pregnancies with children is suggested. It is also important to determine the possible effects of immunosuppressive drugs in children who have undergone this treatment during pregnancy until they are adults. To recognize and acknowledge the risks and obligations associated with immunosuppressive medications, this multidisciplinary strategy for Planned Parenthood must be addressed with the couple.

Introduction

Monoclonal antibodies (mAbs) are produced from the same, single B-lymphocyte clone which have a high specificity of recognition to the same epitope of an antigen (Nelson et al., 2000). Methods to produce specific antibodies or immunoglobulins involving human–mouse hybrid cells were first introduced by Schwaber and Cohen (1973). Subsequently, Kohler and Milstein (1975) introduced the hybridoma technique which enable a large production of mAbs. Their effort has earned them the prestigious Nobel Prize in Physiology or Medicine 1984. Unfortunately, the immunogenicity of the murine mAbs has limited their clinical applicability in human. To eliminate this major limitation, the technology has expanded and moved away from animal models to a humanization mAbs production.

A parallel increase in the knowledge of diseases pathology and a rapid progress in the antibody engineering have further accelerate the therapeutic use of mAbs. The specific selectivity of mAbs enables personalized medicine as the desired therapeutic outcomes can be achieved using a more targeted therapy, while minimizing the undesirable side effects of the non-specific, broad-spectrum conventional therapeutic agents. This chapter summarizes the history and development of mAbs, as well as their clinical use and the associated adverse events.

Development and production of monoclonal antibody

The first production of monoclonal antibodies (mAbs) is through hybridoma technique that was introduced by Kohler and Milstein (1975). This initial method uses mice to produce a large number of mAbs, as illustrated in Fig. 1. Unfortunately, the potent immunogenicity of the murine mAbs has hampered the clinical application in human due to the adverse events, particularly severe hypersensitivity reactions. The human anti-mouse antibody (HAMA) reaction also leads to reduce efficacy or treatment resistant in the host. To overcome these limitations, mAbs production via hybridoma method was later revolutionized from murine to chimeric antibodies which combine sequences of the murine variable domain with human constant region domain (Morrison et al., 1984).

The hybridoma technique is also expanded to generate humanized antibodies and the first success was achieved through the fusion of human spleen cells from patients with human myelomas in 1980 (Olsson and Kaplan, 1980). Generation of humanized antibodies are achieved by the complementary-determining region (CDR) grafting technique. In CDR grafting, non-human antibody CDR sequences are transplanted into a human framework sequence in order to maintain target specificity (Jones et al., 1986).

The hybridoma technique was the main production method of mAbs in the early stage of clinical development (1985–1996). However, this method has a relatively low efficiency with high risk of contamination (Beerli and Rader, 2010). Other barriers

Fig. 1 The hybridoma technique in producing monoclonal antibodies first involves inoculation of the desired antigen (immunization) into mice to produce antibody-specific plasma cells. Subsequently fusion of the plasma cells and myeloma cells are performed using the electrofusion or polyethylene glycol. Selection of the hybridoma cells is performed in the hypoxanthine-aminopterin-thymidine (HAT) medium culture and finally after antibody screening and expansion, the monoclonal antibodies are harvested. The harvested antibodies undergo chimerization or complementary-determining region (CDR) grafting for antibody humanization.

include limitation in obtaining the lymphocyte cells as it was unethical to immunize patients with experimental antigen and therefore the early stage of clinical human mAbs trials were limited to infectious diseases and malignancies (Nelson et al., 2010).

The introduction of phage display method in the 1990s has provided a key discovery technology to obtain fully human mAbs (Lu et al., 2020). This technique was first introduced by George P. Smith in 1985, which can be used to evolve new proteins (Smith, 1985). Subsequently Sir Gregory Winter applied phage display for the discovery and isolation of antibodies, with the aim of producing new pharmaceuticals (McCafferty et al., 1990). Both of them were awarded with The Nobel Prize in Chemistry 2018 for their work and contributions. Phage display is the first *in vitro* antibody selection technique which does not require *in vivo* immune response via immunization. It involves incorporation of the genes which encode protein of interest into filamentous bacteriophages. The proteins, peptides or antibodies encoded by the gene were then displayed on the surface as illustrated in Fig. 2. This technique enables a rapid identification of peptides or antibody fragments, such as single chain fragment variable (scFv) or Fab, that bind a variety of target molecules (proteins, cell-surface glycans and receptors). The library can be used to generate new antibodies to almost every type of antigen and to a broader range of epitopes. Antibodies to toxic antigens that could not be used to immunize an animal can also be produced (Wu et al., 2016; Frenzel et al., 2016).

The production of fully human mAbs are also enabled through the production of antibodies from transgenic mice (Jakobovits, 1995) and single human B cell cloning techniques (Smith et al., 2009). In transgenic mice method, the mice were genetically modified with insertion of human immunoglobulin (Ig) genes into the genome, replacing the endogenous IgG. Hence the mice are capable of synthesizing fully human antibodies upon immunization, as illustrated in Fig. 3 (Jakobovits, 1995). Meanwhile, in the single B cell cloning technique, peripheral blood mononuclear cells (PBMCs) or lymphoid tissues from the infected or vaccinated donors undergo isolation of the single B cells with antigen of interest by flow cytometry. Subsequently amplifications of the immunoglobulin (Ig) heavy chain (VH) and corresponding light chain (VL) domain genes are performed through a reverse transcription-polymerase chain reaction (RT-PCR). The genes are then cloned into mammalian expression vectors for the *in vitro* production of recombinant monoclonal antibodies (Wardemann and Busse, 2019). The generations of humanized and fully human antibodies have accelerated the approvals of various therapeutic mAbs which have a better clinical tolerance in chronic diseases particularly autoimmune disease and malignancy (Lu et al., 2020). Fig. 4 illustrates the evolution of monoclonal antibody productions from murine to fully human antibodies.

Fig. 2 Phage display is a process in which exogenous genes are incorporated into filamentous bacteriophages to compose a library of new proteins or peptides or antibodies that are encoded by the modified genes which are presented on the phage surface. The library is then exposed to an immobilized target such as receptor or enzyme to promote a specific binding. Washing process is subsequently performed to remove the unbound phage to isolate high affinity binders, followed by elution of the bound phage. Subsequently bacteria (*E. coli*) are infected with the eluted phage and amplification take place. Process is repeated two to three times resulting in enriched population of antibody/peptide fragments for the antigen of interest.

Fig. 3 In transgenic mice, the mice were genetically modified such that human immunoglobulin (Ig) genes were inserted into the genome, and making these animals capable of synthesizing fully human antibodies upon immunization with the desired antigens.

Fig. 4 Overview of the evolution from murine antibodies (black domains) to fully human antibodies (gray domains) and associated suffixes. (A) The murine monoclonal antibody. (B) The chimeric monoclonal antibody: variable regions (V_H and V_L) are of murine origin while the rest of the chains are of human origin. (C) Humanized monoclonal antibody: only includes the hypervariable segments of murine origin-95% homology to human antibody. (D) Human monoclonal. C_{H1}: domains of the constant region of the heavy chain; C_L: constant domain of the light chain; Fab and Fc: fragments resulting from proteolysis; V_H: variable domain of the heavy chain; V_L: variable domain of the light chain.

Immunodiagnostic use of monoclonal antibody

Monoclonal antibodies have tremendous applications as diagnostic tools due to their exquisite specificity in the identification, quantitation or localization of particular molecules, cells or organisms in tissue or body fluids (Siddiqui, 2010). The advances in the mAbs production technology allow novel approaches to rapid and accurate diagnosis of infectious, autoimmune, and malignant diseases. There are various diagnostic methods in which mAbs are utilized such as western blot, immunodot blot, enzyme-linked

immunosorbent assay (ELISA), radioimmuno assay (RIA), flow cytometry, immunohistochemistry, fluorescence microscopy, electron microscopy, confocal microscopy, as well as other biotechnological applications. Monoclonal antibodies have been established as invaluable tools in clinical laboratory diagnostic applications including detections and measurements of extensive range of hormones (Payne et al., 1988) and as blood typing reagents (Marks, 2014).

In infectious diseases, monoclonal antibodies provides rapid identifications of the pathogens by either directly detecting the pathogenic antigens or indirectly by detecting the antibodies against the pathogens (Harris, 1987). This immunodiagnostic technique provides a rapid diagnosis with a high sensitivity and specificity, and therefore has replaced the traditional tissue culture in many diseases including viral, bacterial, protozoa and parasitic infection (Siddiqui, 2010). In the era of new or rare infectious agents, mAbs play crucial role in the rapid identification, diagnosis and monitoring to facilitate public health measure to avoid further spread of the infection. For example Ebola viral antigen can be detected in serum as early as the first day of symptoms and thus enable early intervention (Broadhurst et al., 2016). In this current era of COVID-19 pandemic, there is a spurt in research on the utilization of mAbs to aid in the diagnosis as well as monitoring the immunity or response to treatment (Thomas et al., 2021; Carter et al., 2020).

Monoclonal antibodies have a robust diagnostic application in the oncology field. The ability of the mAbs in identifying and localizing particular molecules in cells, tissues or body fluids have permitted a rapid cancer diagnosis with high accuracy, sensitivity, reproducibility and specificity (Zhang et al., 2014). The sensitivity and specificity of immunohistochemistry are enhanced with the aid of mAbs as compared to the conventional H&E staining procedure alone (Payne et al., 1988). In hematological malignancies, mAbs are utilized to different markers can facilitate the diagnosis of T and B cell lymphomas, histiocytic lymphomas, malignant histiocytosis, and Hodgkin's disease (Klavins, 1987). In solid organ cancers, the mAbs have been used to detect various tumor markers such alpha fetal protein (AFP) for liver cancer, prostate specific antigen (PSA) for prostatic cancer and CA 125 for ovarian cancer (Klavins, 1987).

Apart from the conventional pre-existing tumor markers, recent advances in cancer proteomics have led to many new diagnostic methods of cancers. The discoveries of tumor-associated antigens (TAAs) help in a better understanding of disease biology, early detection, discrimination of tumors and monitoring of disease progression (Alhamdani et al., 2009). With the discoveries, mAbs aid in the cancer diagnosis by their utilizations in the antibody-based microarrays to detect tumor-associated antigens (TAAs). For instance a number of proteins that show increased expression levels in malignant breast tissues such as casein kinase 1 ϵ , p53, annexin XI, CDC25C, eIF-4E and MAP kinase 7 have been identified using a high-throughput protein microarray system which contains 378 well-characterized mAbs (Hudelst et al., 2004).

In the field of imaging of cancers, mAbs with high affinity to the tumor markers or proteins have replaced the polyclonal antibodies as radioimmunodetection probes, in order to precisely diagnose and locate the cancers at early stage (Rudnick and Adams, 2009). Before the year 2000, single-photon emission computed tomography with mAbs used to be one of the methods to diagnose various solid organ cancers such as ovarian, colorectal, lung, and prostatic cancers (Goldenberg, 1997). Subsequently, the fluorine-18 fluorodeoxyglucose positron emission tomography (18F-FDG PET) has emerged as a standard radionuclide imaging as it provides higher contrast images and better resolutions in locating the lesions. Nonetheless, more recent studies have expanded the application of these radiolabeled antibodies in the management of malignancies. The combination of PET imaging with zirconium-89 radiolabeled mAbs, also known as 89Zr-immuno-PET, provides a non-invasive tool in a whole body assessment of the tumor's target expression and tumor targeting (Garousi et al., 2020). This tool can be used to facilitate personalized treatment with prediction of the efficacy and toxicity of tumor treatment (Jauw et al., 2016). With the development of antibody-drug conjugates (ADCs), PET-immuno method can be utilized to verify the delivery of targeted agents to tumors (Carmon and Azhdarinia, 2018). Apart from malignancies, this new technology may also be applied in other conditions such in disseminated infections of invasive aspergillosis (Thornton, 2018).

Therapeutic use of monoclonal antibody

In the last few decades, the therapeutic use of monoclonal antibody has expanded and emerged as one of the predominant treatment modalities for various diseases, including autoimmune diseases, transplantation, oncology, cardiovascular, and infectious diseases (Lu et al., 2020). The use of monoclonal antibodies has become one of the major breakthroughs in medicine as it has paved the era of personalized therapy due to their effectiveness and precisions. Until 2020, more than 550 mAbs are in the pipeline of clinical trials (Kaplun et al., 2020) and up to February 2020, a total of 82 mAbs obtained United States Food and Drug Administration (FDA) or European Medicine Agencies (EMA) approval for therapeutic use in humans (de la Torre and Albericio, 2021).

Solid organ transplantation

Solid organ transplantation provides a "new life" for many patients as it restores self-body functions, improves quality of life and life expectancy (Rana et al., 2015). Preventing rejection of the allograft is the ultimate goal to ensure short- and long-term success and this is achieved by attaining tolerance state in the host via immunosuppression. Unfortunately, the complexity of the immune system as well as the toxicity of the conventional immunosuppressive agents have become a great barrier to achieve the allograft tolerance goal. With the discoveries of mAbs production, they are utilized in various settings in transplant such as: (i) an induction

Fig. 5 Muromonab targets the CD3 protein on the surface of circulating human T cells, which is part of the T-cell receptor (TCR) complex which induces T-cell apoptosis. Basiliximab and daclizumab prevent the binding of the IL-2 to its receptor (CD25) causing interruption in the cascade of cell activation, proliferation and cytokine release. Alemtuzumab is directed against the cell surface glycoprotein CD52 on the surface of mature lymphocytes, causing an antibody-dependent lysis of lymphocytes. Rituximab binds to CD20 antigen on the surface of B-cell and induces cytotoxicity. Abatacept and belatacept are the co-stimulation blockers of T cells by inhibiting the bindings of CD28 and CTLA-4 to CD80 and CD86. Eculizumab is directed against the complement protein C5, thereby inhibiting conversion of C5 to C5b and preventing formation of the membrane attack complex (C5–9).

therapy (a period of intense immunosuppression before and following the implant of the allograft), (ii) sparing agents against the toxicity of the conventional immunosuppressive agents, (iii) treatment of acute allograft rejection and (iv) mitigation of the effects of delayed graft function (Pilch et al., 2019).

Solid organ transplant is the pioneer field that has obtained approval of the first mAb to be used clinically in human. Muromonab-CD3 (Orthoclone OKT3, Janssen-Cilag, Beerse, Belgium) is a murine immunoglobulin which targets against CD3 on the surface of circulating human T cells, which is part of the T-cell receptor complex. It subsequently blocks the generation and function of cytotoxic T cells (Norman and Leone, 1991). However, muromonab was discontinued in 2010 with the wide availability of the chimeric (basiliximab) and humanized (daclizumab) mAbs. Both agents have better efficacy with lesser immunogenicity and side effects, including fewer opportunistic infections and malignancies (Olyaei et al., 2001). Basiliximab and daclizumab prevent the initial steps of antigen recognition by binding with high affinity to the interleukin-2 receptor (CD25) hence blocking the subsequent T cell clonal expansion. It is widely used as an induction agent with the aim to reduce risk of delayed graft function, minimize impact of acute graft rejection and prolong graft survival. It also minimizes the toxicity of calcineurin inhibitor (CNI) as it allows lower dose of CNI or delaying the CNI initiation until the patient has developed graft function. Belatacept, a selective T-cell costimulation blocker is indicated for prophylaxis of organ rejection in adult patients receiving a kidney transplant. It is a fusion protein composed of the Fc fragment of human IgG1 linked to the extracellular domain of cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4), selectively inhibits T-cell activation through costimulation blockade (Vincenti et al., 2016).

Other mAbs such as alemtuzumab (anti-CD52), abatacept (CTLA4-Ig fusion protein, co-stimulation blocker of T cells), rituximab (anti-CD20), bortezomib (proteasome inhibitor) and eculizumab (anticomplement C5) are also used in solid-organ transplant. Fig. 5 illustrates the mAbs main mechanism of actions in transplant.

Autoimmune diseases

The advances in the understanding of the pathogenesis of autoimmune diseases have led to the identifications of their pathogenic inflammatory molecules. Parallel to the progress in the mAbs technology, the therapeutic approach in autoimmune disease has witnessed a significant paradigm shift by utilization of mAbs to target against specific inflammatory molecules or immune pathways.

Since many autoimmune diseases are associated with particular human leukocyte antigens, the initial attempts to use mAbs in the treatment of autoimmune disease involved antibodies directed against major histocompatibility antigens (MHA II) (Wofsy, 1985). Unfortunately, the widespread expression of MHA II and the broad effects on both B and T cells became a significant barrier to their clinical applications. Subsequently, antibodies to T cell antigens such as CD4-directed antibodies were investigated for the treatment of several autoimmune diseases such as in rheumatoid arthritis (Herzog et al., 1987) and multiple sclerosis (Hafler et al., 1988). However, despite significant clinical improvement in RA, severe CD4 lymphopenia, and skin rashes lead to discontinuation of treatment (Choy et al., 2002).

Subsequent successful therapeutic trials consist of specific mAbs against inflammatory cytokines. Infliximab, a chimeric monoclonal antibody against the tumor necrosis factor- α (TNF- α), became the first to be licensed in Crohn's disease in 1998. Its use was later has been successfully employed in the treatment of other autoimmune diseases such as rheumatoid arthritis, psoriasis, ankylosing spondylitis, psoriatic arthritis, and ulcerative colitis. However, to overcome its immunogenicity, Adalimumab (Humira), another monoclonal antibody of fully human origin was derived by a phage display library and used to treat RA patients (Bacquet-Deschryver et al., 2008). Since then, many other cytokine blockade mAbs have emerged such as interleukin-6 (IL-6), interleukin 1 (IL-1), IL-17 and IL-22/23 inhibitors. In addition, B cell depletion therapies mediated via CD20 and CD22, inhibition of B cells survival factors (BAFF and APRIL) and inhibition of B-T cell interactions in autoimmune diseases are also achieved through mAbs. Table 1 summarizes the monoclonal antibodies that are approved to be used in various autoimmune diseases and inflammatory diseases.

Malignancies and cancers

Continuous progression in the understanding in carcinogenesis, molecular biology and technology have opened novel management pathways by utilizing mAbs to direct against multiple targets that are involved in the cancer cells progression and survival. Unlike the conventional chemotherapy which has a wide non-specific cytotoxic effects, antibody-based therapies have a specific direct cytotoxicity of the tumor cells while sparing the normal host cells through various mechanisms such as receptor blockade, immune-mediated cell killing via antibody and complement-dependent cellular cytotoxicity phagocytosis, payload delivery and specific effects on the tumor vasculature and stroma (Scott et al., 2012).

There are many mAbs that are used to treat different types of cancer. The mAbs can serve as targeted cancer therapy. They can recognize and bind specifically to tumor antigens of tumor-specific antigen (TSA) (Bubeník et al., 1973) or tumor-associated antigen (TAA) (Hollinshead et al., 1985) that are present on cancer cells surface and malignant sites thus produced immune responses that lead to cell death to eradicate the tumor (Johdi and Sukor, 2020) (Fig. 6). TSAs are a group of mutated proteins due to somatic mutations and relatively are restricted to tumor cells (Dickinson et al., 1973). Their specificity in tumor cells makes them a good candidate for immunotherapy. One of the good examples of a TSA is the mutated p53 protein that is present in many cancer cells. In contrast, TAAs have differentially expressed proteins that are present in both malignant and non-malignant cells. Although TAAs are also expressed on normal cells, their expression on malignant cells has a unique characteristic and highly expressed resulting in specific immunogenicity (Alatrash and Molldrem, 2019). The binding of mAbs to TSA or TAA produces molecular signals to immune cells such as T cells, B cells and natural killer cells. This further initiates and activates receptors activities that lead to apoptosis and tumor-killing (Scott et al., 2012; Michaud et al., 2014). Thus, mAbs are also a form of immunotherapy because they help enhance the host immune system against cancer.

Some mAbs are able to mark cancer cells which facilitate host immune system to recognize and destroy cancer cells. Other mAbs are capable of guiding the immune cells such as T cells close to cancer cells, thus helping these immune cells in cancer cells killing. There are many effector mechanisms of cancer cell killing by mAbs. The main method is through direct effector mechanism where the mAbs bind to their target growth factor receptors and manipulate their activation state or block ligand binding. This is the common form and there are several FDA approved of mAbs of this form, as illustrated in Table 2 (US Food and Drug Administration, 2021). For example, epidermal growth factor receptor (EGFR) which is overexpressed by many different cancers. EGFR is crucial for cell signaling that leads to tumor cell proliferation, migration and invasion. Cetuximab, which is an anti-EGFR mAb binds to EGFR and blocks ligand binding and receptor dimerization and ultimately induces apoptosis in tumor cells (Patel et al., 2009). The second effector mechanism is through indirect mechanisms of mAbs which require the engagement of components of the host immune system such as complement-dependent cytotoxicity (CDC), antibody-dependent cellular phagocytosis (ADCP) and antibody-dependent cellular cytotoxicity (ADCC). Some mAbs such as rituximab depends on CDC for its in vivo efficacy. In a preclinical model, a knockout of the complement cascade component C1q completely abolished rituximab anti-tumor effects showing the dependency of this mAbs of the complement component (Di Gaetano et al., 2003). The ADCP form occurs when Fc γ RI component expressed on immune cells such as macrophages binds to IgG1 or IgG3 mAbs that have opsonized a tumor cell. However, there are very limited reports on this form of indirect effector mechanism although its important role in destruction of circulating tumor cells following mAb therapy cannot be denied (Gül et al., 2014).

Another indirect effector mechanism is through ADCC which was described in 1965 by Erna Möeller. In ADCC approach, the cancer cells are opsonized by mAbs which then recruits effector cells to induce target cell death by non-phagocytic mechanisms (Moeller, 1965). In this case, the mAbs act as a bridge by binding to antigens on the target cell surface via their Fab portions and linking the effector cells via their Fc portions. Of all the IgG classes, IgG1 is the most relevant subclass for this type of anti-cancer

Table 1 Monoclonal antibodies that are approved to be used in autoimmune and inflammatory diseases.

<i>Monoclonal antibody</i>	<i>Target</i>	<i>Disease (year approval)</i>
Infliximab	TNF α ; chimeric IgG1	Crohn's disease (1998) Rheumatoid arthritis (1999) Ankylosing spondylitis (2004) Psoriatic arthritis (2005) Ulcerative colitis (2005) Psoriasis (2006)
Etanercept	TNF α ; TNFR2 with Fc portion of human IgG1	Rheumatoid arthritis (1998) Polyarticular JIA (1999) Psoriatic arthritis (2002) Ankylosing spondylitis (2003) Psoriasis (2004)
Adalimumab	TNF α ; human IgG1	Rheumatoid arthritis (2002) Psoriatic arthritis (2005) Ankylosing spondylitis (2006) Crohn's disease (2007) Psoriasis (2008) Ulcerative colitis (2012) Hidradenitis suppurativa (2015) Uveitis (2016)
Certolizumab pegol	TNF α ; humanized IgG Fab fragment	Crohn's disease (2008) Rheumatoid arthritis (2009) Psoriatic arthritis (2013) Ankylosing spondylitis (2013) Psoriasis (2018) Non-radiographic spondyloarthritis (2019)
Golimumab	TNF α ; human IgG1	Rheumatoid arthritis Psoriatic arthritis Ankylosing spondylitis
Anakinra	IL-1R recombinant receptor antagonist	Rheumatoid arthritis (2001) Cryopyrin-associated periodic syndromes (2013)
Canakinumab	IL-1 β ; human IgG1	Cryopyrin-associated periodic syndrome (2009) Systemic JIA (2013) Periodic fever syndromes (2016) AOSD (2020)
Ustekinumab	IL-12/IL-23; human IgG1	Psoriasis (2009) Psoriatic arthritis (2013) Crohn's disease (2016) Ulcerative colitis (2019)
Guselkumab	IL-23; human IgG1 λ	Psoriasis (2017)
Tocilizumab	IL-6R; human IgG1	Rheumatoid arthritis (2010) Systemic JIA (2011) Polyarticular JIA (2013) Giant cell arteritis (2017) CAR T cell-induced cytokine release syndrome (2017)
Sarilumab	IL-6R; human IgG1	Rheumatoid arthritis (2017)
Secukinumab	IL-17A; human IgG1	Psoriasis (2015) Ankylosing spondylitis (2016) Psoriatic arthritis (2016) NR-axial sPA (2020)
Ixekizumab	IL-17A; human IgG4	Psoriasis (2016) Psoriatic arthritis (2017) Radiographic axial sPA (2019) NR-axial sPA (2020)
Brodalumab	IL-17A; human IgG2	Psoriasis (2017)
Rituximab	CD20; chimeric IgG1	Rheumatoid arthritis (2006) Granulomatous polyangiitis and microscopic polyangiitis (2011) Phemphigus vulgaris (2018)
Belimumab	BLyS; human IgG1	SLE (2011)
Ocrelizumab	CD20; humanized IgG1	Multiple sclerosis (2017)
Abatacept	CTLA4-Ig fusion protein; IgG1	Rheumatoid arthritis (2005)

(Continued)

Table 1 (Continued)

<i>Monoclonal antibody</i>	<i>Target</i>	<i>Disease (year approval)</i>
Efalizumab	CD11a; humanized IgG1	Psoriatic arthritis (2017)
Vedolizumab	Integrin- $\alpha 4\beta 7$; humanized IgG1	Psoriasis (2003, withdrawn 2009)
Natalizumab	VLA-4; humanized IgG4	Ulcerative colitis and Crohn's disease (2014)
		Multiple sclerosis (2004)
		Crohn's disease (2008)
Alemtuzumab	CD52; humanized IgG1	Multiple sclerosis (2014)
Eculizumab	Complement C5; humanized IgG2/4	Paroxysmal nocturnal hemoglobinuria (2007)
		Atypical hemolytic uremic syndrome (2011)
		Generalized myasthenia Gravis (2017)
		Neuromyelitis optica spectrum disorder (NMOSD) (2019)
Mepolizumab	IL-5; humanized IgG1	Asthma (2015)
		EGPA (2017)
Reslizumab	IL-5; humanized IgG4	Asthma (2016)
Dupilumab	IL-4R α ; human IgG4	Eczema (2017)
		Asthma (2018)
		Atopic dermatitis (2019)
		Chronic rhinosinusitis with nasal polyposis (2019)
Omalizumab	IgE; humanized IgG1	Asthma (2003)
		Chronic urticaria (2014)
		Nasal polyps (2020)
Emapalumab	IFN γ	Primary hemophagocytic lymphohistiocytosis (2018)

Fig. 6 Monoclonal antibodies in cancer. Monoclonal antibodies (mAbs) such as cetuximab are designed to target tumor-associated antigens (TAAs) or tumor-specific antigens (TSAs) that are abundant in cancer cells surface. The signals produced by receptor activities mediated immune cells toward malignant sites thus produced immune responses that lead to cell death to eradicate the tumor (Johdi and Sukor, 2020).

therapeutic antibodies (Teillaud, n.d.). The effector cells must express FcR that will bind to mAbs in order to facilitate ADCC (Fanger et al., 1989). NK cells are the main effector type that mediate ADCC; however other myeloid types such as monocytes, macrophages, neutrophils, eosinophils, and dendritic cells are also capable (Fanger et al., 1989). Effector cells induce target cell death via cytotoxic granule release, Fas signaling, and initiation of reactive oxygen species.

The use of mAbs against the immune checkpoint proteins have also unlocked the new era of immunotherapy in malignancy. Recently discovered proteins such as the programmed cell death protein 1 (PD-1) and its ligand programmed death-ligand 1 and 2 (PD-L1, PD-L2) or cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4, ipilimumab) have been the targets of the mAbs in treating various cancers (Graybrot et al., 2019). Fig. 7 illustrates the approved mAbs which targets these immune checkpoints, and their mechanism of actions.

Infection and COVID-19

The use of antibodies from sera of infected humans have been used as treatment for viral infections since the early 20th century. Its first therapeutic use against diphtheria by Paul Ehrlich and Emil von Behring has led them to win the Nobel Prize in Physiology or Medicine in 1908 (Ehrlich, 1954). This treatment was gradually replaced by purified antibodies obtained from pooled sera, intravenous immunoglobulin (IVIG) (Stangel and Pul, 2006). Subsequently, the rapid advances from hybridoma technique to phage display library and single B-cell or plasma cell secreting antibody in mAb productions have led to the development of several mAbs to treat infection.

Table 2 List of FDA-approved monoclonal antibodies in treating various types of cancers.

Target	FDA approved monoclonal antibody	Trade name	Manufacturer	Type of cancer treated	Year of approval and updates
HER-2 and HER-2/neu	Trastuzumab	Herceptin [®]	Genentech	Breast cancer	1998
				Gastric cancer	2006
				Breast cancer	2010
	Ado-trastuzumab emtansine	Kadcyla [®]	Genentech	Breast cancer	2013
				Breast cancer	2019
	Pertuzumab	Perjeta [®]	Genentech	Breast cancer	2012
				Breast cancer	2013
				Breast cancer	2017
	Fam-trastuzumab deruxtecan	Enhertu [®]	Daiichi Sankyo	Breast cancer	2019
				Gastric/gastroesophageal cancer	2021
CD20	Margetuximab	Margenza [®]	MacroGenics	Breast cancer	2020
				Non-Hodgkin lymphoma	2006
	Rituximab	Rituxan [®]	Biogen IDEC and Genentech	Non-Hodgkin lymphoma	1997
				Chronic lymphocytic leukemia	1997
				Chronic lymphocytic leukemia	2010
	Ibritumomab tituxetan	Zevalin Y-90 [®]	IDEC Pharmaceuticals	Non-Hodgkin lymphoma	2002
				Non-Hodgkin lymphoma	2003
	Tositumomab	Bexxar [®]	GlaxoSmithKline	Chronic lymphocytic leukemia	2009
				Chronic lymphocytic leukemia	2016
	Ofatumumab	Arzerra [®]	GlaxoSmithKline	Chronic lymphocytic leukemia	2013
Chronic lymphocytic leukemia				2019	
Chronic lymphocytic leukemia				2016	
EGFR	Cetuximab	Erbix [®]	ImClone Systems	Colorectal cancer	2004
				Head and neck cancer	2011
	Panitumumab	Vectibix [®]	Amgen	Colorectal cancer	2006
				Colorectal cancer	2014
Necitumumab	Portrazza [®]	Eli Lilly and Company	Squamous non-small cell lung cancer	2017	
			Squamous non-small cell lung cancer	2015	
			Squamous non-small cell lung cancer	2015	
GD2	Dinutuximab	Unituxin [®]	United Therapeutics	Neuroblastoma (pediatric)	2015
				Neuroblastoma (pediatric)	2020
VEGFR2	Naxitamab	Danyelza [®]	Y-mAbs Therapeutics	Neuroblastoma (pediatric)	2020
				Gastric cancer	2014
	Ramucirumab	Cyramza [®]	Eli Lilly and Company	Non-small cell lung cancer	2014
				Non-small cell lung cancer	2020
CD38	Daratumumab	Darzalex [®]	Janssen Biotech	Colorectal cancer	2015
				Hepatocellular carcinoma	2019
				Multiple myeloma	2015
	Isatuximab	Sarclisa [®]	Sanofi-aventis	Multiple myeloma	2016
				Multiple myeloma	2017
				Multiple myeloma	2018
				Multiple myeloma	2019
CD33	Gemtuzumab ozogamicin	Mylotarg [®]	Pfizer	Multiple myeloma	2020
				Multiple myeloma	2020
				Multiple myeloma	2021
CD30	Brentuximab vedotin	Adcetris [®]	Seattle Genetics	Acute myeloid leukemia	2017
				Hodgkin's lymphoma	2011
	Anaplastic large cell lymphoma	Anaplastic large cell lymphoma	Anaplastic large cell lymphoma	2018	
				2011	
CD19	Blinatumomab	Blincyto [®]	Amgen	Precursor B-cell acute lymphoblastic leukemia	2017
				Precursor B-cell acute lymphoblastic leukemia	2018
	Tafasitamab	Monjuvi [®]	MorphoSys US	Diffuse large B-cell lymphoma	2020
				Diffuse large B-cell lymphoma	2021
SLAMF7	Loncastuximab	Zynlonta [®]	ADC Therapeutics SA	B-cell lymphoma	2021

Fig. 7 Mechanism of actions various monoclonal antibodies as immune checkpoint inhibitors. The binding of checkpoint protein PD-L1 on tumor cells to PD-1 on T cells prevents T-cell from killing the tumor cell. Blocking the binding of PD-L1 to PD-1 with an immune checkpoint inhibitor (anti-PD-L1, e.g., atezolizumab or anti-PD-1, e.g., pembrolizumab and nivolumab) activates the T cells to kill tumor cells. The binding of B7-1/B7-2 on antigen presenting cell to CTLA-4 on T cell leads to the inactivation of T-cell mediated tumor cell killing. Blocking the binding of B7-1/B7-2 to CTLA-4 with an immune checkpoint inhibitor (anti-CTLA-4 antibody, e.g., ipilimumab) allows the T cells to be active and to kill tumor cells.

In 1990s several monoclonal antibodies were developed as a treatment strategy in bacterial sepsis and viral infections. The antibodies are directed against the inflammatory cytokines in sepsis, targeting the toxic products of the infecting organism, and specifically against circulating endotoxin (the lipopolysac-polyclonal antiserum⁶ 17 and monoclonal antiendotoxin anticharide component of the bacterial cell wall. Unfortunately the initial evaluations of their clinical benefit in human studies were not demonstrated and thus may have dampened the enthusiasm of researchers and investors in exploring the utilizations of mAbs in bacterial infection (Zurawski and McLendon, 2020). Similarly, majority of studies on mAbs for the treatment and prophylaxis of other viral infections such as CMV, HIV, Influenza, MERS-COV and Zika did not show any significant efficacy in clinical trials. Of these, only monoclonal antibodies targeting respiratory syncytial virus (RSV) and Ebola (Mulangu et al., 2019) have been shown to be effective in human trials.

With the current pandemic COVID-19 secondary to the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection, there are emerging treatment in combating this devastating disease. The initial studies and clinical trials involve re-purposing of the pre-existing mAbs and they are mainly directed toward controlling the hyper-active immune response or the cytokine storm of COVID-19 to save the lives of patients. In patients with severe COVID-19, a raised level of various cytokines and

chemokines including IL-2, IL-6, IL-7, IL-10, IL-17, G-CSF, GM-CSF, IP-10, MCP1, MIP1A, TNF α , IFN- γ , VEGF, CCL2, etc. were found in numerous studies (Yang et al., 2020). Currently, majority of the mAbs that are under clinical trials are IL-6 inhibitors such as tocilizumab (phase 4), sarilumab (phase 3), and siltuximab (phase 3). Other mAbs targeting other cytokines are also still under early phase of clinical trials such as lenzilumab (GM-CSF antagonist), risankizumab (interleukin-23 inhibitor), adalimumab and infliximab (TNF- α inhibitors), canakinumab and anakinra (IL-1 inhibitors) (Deb et al., 2021; de Mello Silva Júnior et al., 2021).

Novel therapy using neutralizing mAbs to SARS-CoV-2 have been developed and are now under evaluation in clinical trials. Neutralizing mAbs are recombinant proteins that can be derived from the B cells of convalescent patients or humanized mice (Taylor et al., 2021). The majority of monoclonal antibody products under development for SARS-CoV-2 target the spike protein, which the virus utilizes to enter host cells such as bamlanivimab, etesevimab, casirivimab and imdevimab (Pinto et al., 2020). Food and Drug Administration (FDA) have granted the Emergency Use Authorizations (EUAs) for combination therapy of bamlanivimab plus etesevimab and casirivimab plus imdevimab for the treatment of mild to moderate COVID-19 in non-hospitalized patients who are at high risk for progressing to severe disease and/or hospitalization.

Other non-communicable diseases

Therapeutic use of mAbs is expanded to other non-communicable diseases including cardiovascular disease. The first chimeric antibody, anti-GPIIb/IIIa antigen-binding fragment (Fab) (abciximab), was approved in 1994 by the US FDA for inhibition of platelet aggregation in cardiovascular diseases. Table 3 illustrates the mAbs that are approved in the treatment of various non-communicable diseases.

Adverse events

Monoclonal antibodies (mAbs) have emerged as targeted therapies for many conditions such as malignancies, transplant rejection, autoimmune and infectious diseases. However, there are several adverse events with the use of monoclonal antibodies and their complications are mainly related to immunomodulation and infection.

Hypersensitivity reactions and immunogenicity

Hypersensitivity reactions to mAbs can be due to the classic type I (IgE/non-IgE), type III, and delayed type IV reactions and cytokine-release reactions (Hong and Sloane, 2019). Fortunately with the revolution of mAbs from murine to more advance humanized and fully human mAbs, these reactions are less common (Nelson et al., 2010). However, in malignancies, the incidence does not appear to correlate with the origin (human, chimeric or mouse) of the drug, which might be explained by the fact that cytokine release is more often the causative factor than classic hypersensitivity type reactions (Rombouts et al., 2020).

Apart from causing various hypersensitivity reactions, immunogenicity of the mAbs and the development of antidrug antibodies (ADAs) can also affect the efficacy of the therapeutic agent. This immunogenicity may also occur in humanized and fully human antibody, likely due to the use of transgenic mouse cell lines, which cannot generate human carbohydrate side chains (Nelson et al., 2010) and alterations in particular amino acids at certain positions can also influence immunogenicity (Hansel et al., 2010).

Immunosuppression

The use of mAbs results in an acquired immunosuppression state and particular types of infections in certain mAbs illustrate the protective function of the target ligand in the normal immune system (Hansel et al., 2010). For example, anti-TNF α causes reactivation of latent tuberculosis infection while rituximab (anti-CD20) may lead to reactivation of hepatitis B infection. The use of eculizumab increased susceptibility to encapsulated organisms such as Meningococcal and Neisseria infection.

Table 3 List of FDA-approved monoclonal antibodies in treating various non-communicable diseases.

Monoclonal antibody	Target	Disease (year of approval)
Ranibizumab	Vascular endothelial growth factor A (VEGF-A); humanized IgG1 Fab fragment	Neovascular (wet) age-related macular degeneration (2006) Macular edema due to retinal vein occlusion (2010) Diabetic macula edema (2015) Myopic choroidal neovascularization (2017) Diabetic retinopathy (2017)
Denosumab	Receptor activator of nuclear factor kappa-B ligand (RANKL); human IgG2	Osteoporosis (2010)
Alirocumab	Proprotein convertase subtilisin/kexin type 9 (PCSK9)	Hypercholesterolemia (2015)
Evolocumab	Proprotein convertase subtilisin/kexin type 9 (PCSK9)	Prevent heart attack and stroke (2017)
Erenumab	Calcitonin gene-related peptide receptor (CGRPR)	Migrain (2018)

The occurrence of progressive multifocal leucoencephalopathy (PML) due to the reactivation of latent infection in the central nervous system with the polyoma virus John Cunningham (JC) virus infection has been described in natalizumab in patients with multiple sclerosis and Crohn's disease (Major, 2009). Cases have also been described with rituximab (Carson et al., 2009) and infliximab (Kumar et al., 2010).

Other reported opportunistic infections with mAbs include bacterial and fungal opportunistic infections, such as histoplasmosis, listeriosis, aspergillosis, candidiasis, *Pneumocystis carinii* pneumonia and coccidioidomycosis (Descotes, 2009).

Emergence of autoimmune diseases

Monoclonal antibody that targets TNF- α has been associated with the development of anti-nuclear antibodies, antibodies to double-stranded DNA, and also with lupus-like syndromes (Hansel et al., 2010). Demyelinating disease or multiple sclerosis have also been reported with anti-TNF- α therapy (Paul and Koffman, 2018) while immune thrombocytopenic purpura, thyroiditis has been reported in alemtuzumab (Hansel et al., 2010). Paradoxical immune reactions causing psoriasis, hidradenitis suppurativa has been reported with the use of mAbs (Casanova Estruch, 2013).

The use of immune-checkpoint inhibitors in cancers such as anti-cytotoxic T lymphocyte antigen 4 (CTLA-4), anti-programmed cell death 1 (PD-1) and anti-programmed cell death 1 ligand 1 (PD-L1) mAbs has led to the development of a new spectrum of immune-related adverse events (irAEs) (Martins et al., 2019). In contrast to the lupus-like syndrome cause by anti-TNF, irAEs tend to affect major organs and the most frequently affected organs are colitis, myocarditis, encephalitis and pneumonitis, which could be life-threatening.

Malignancy

There's emerging concern on the increased risk of malignancy with mAbs particularly anti-TNF α , due to its pleiotropic effects upon different stages of tumor genesis and TNF inhibition may influence the natural history of cancer progression (Balkwill, 2009). However, a recent substantial evidence has demonstrated no increased risk of cancer with anti-TNF (Mercer et al., 2015; Mariette et al., 2011; Limketkai, 2020).

Rituximab therapy is associated with increased risk of secondary solid tumors in patients with lymphoma (Tarella et al., 2011). However, no increased risk of malignancy with its use among patients with rheumatoid arthritis (Emery et al., 2020), suggesting possible other risk factors in the development of secondary malignancy.

Cardiotoxicity

Concerns have been raised regarding an increased risk of major adverse cardiovascular events (MACEs) (myocardial infarction, cerebrovascular accident or cardiovascular death) in patients treated with mAbs in patients with rheumatic diseases. However, the evidence is conflicting as some studies report a lower risk of cardiovascular events, while others report no significant difference (Lee et al., 2018). On the other hand, cardiotoxicity is one of the well-established consequences of the human epidermal growth factor receptor- (HER2-) targeted therapies such as trastuzumab, lapatinib, pertuzumab, and ado-trastuzumab emtansine. The use of immune checkpoint inhibitors are also associated with various cardiotoxicity such as hypertension, heart failure and prolonged QT syndrome (Dong and Chen, 2018).

Conclusion

Monoclonal antibody is an illustration of a remarkable translational scientific discovery and its bench-to-bedside journey took around a decade to be materialized into the clinical application of its use. However, a balance between the cost of treatment, efficacy and safety need to be considered as the treatment with mAbs can be expensive. Hence, more robust data on their cost effectiveness and long-term safety are warranted. Major advances in genetic sequencing and biomedical research have led to more on-going research of monoclonal antibodies in identifying new targets while optimizing their efficacy and safety for use in clinical practice.

Introduction

Cytokines are low-molecular weight (usually below 30 kDa) secreted proteins. The term cytokine is derived from the Greek and means cell movement ('*cyto*,' cell; '*kinos*,' movement). As the name implies, cytokines stimulate the movement of cells and help interaction and communication between them. They are secreted primarily by immune cells such as helper T cells (Th cells), macrophages, and dendritic cells; however, they can also be produced by non-immune cell types in response to infection or damage (Muñoz-Carrillo et al., 2018). Cytokines act on their target cells in various ways, either on cells that secrete them (autocrine action), on nearby cells (paracrine action), or they act in an endocrine fashion, i.e. on distant cells. Moreover, cytokines are characterized by their pleiotropic activity, which means that a single cytokine can have different effects on various cell types. It is common for different cell types to secrete the same cytokine; cytokines are frequently redundant, with different cytokines stimulating similar functions. Moreover, they can synergize with or antagonize (inhibit action) other cytokines. They act through transduction of signals and control many biological processes on various cell types, including cell growth and differentiation, apoptosis, and pro-inflammatory or anti-inflammatory responses. Cytokines stimulate these biological processes by binding with high-affinity to specific receptors on the surface of cells. Upon binding, intracellular signaling pathways are triggered leading to alteration in the levels of gene transcription, and hence, functional changes in these cells. Cytokine-driven stimulation is frequently short-lived.

Common structure and signaling pathways of their receptors allow cytokines to be grouped into families: (i) IL-1 superfamily, (ii) TNF superfamily, (iii) IL-17 family, (iv) IL-6 superfamily, (v) type I cytokine receptor family and, (vi) type II cytokine receptor family (Gadina et al., 2017; Muñoz-Carrillo et al., 2018).

Their ability to induce a potent response against pathogens, but also their involvement in numerous immune and inflammatory states, has led to the development of cytokine-based therapies that will be described in this chapter.

Cytokines and cytokine antagonists as therapeutic agents

IL-1 superfamily

The Interleukin (IL)-1 superfamily consists of the IL-1 family that includes 11 ligands (IL-1 α , IL-1 β , IL-1Ra, IL-18, IL-33, IL-36 α , IL-36 β , IL-36 γ , IL-36Ra, IL-37 and IL-38) and 10 receptors (IL-1R to IL-10R), with both pro-inflammatory and anti-inflammatory functions that are linked to chronic inflammation. Members of the IL-1 family are involved in defense against pathogens by developing immune responses to foreign antigens (Dinarello, 2018).

The most studied member of the IL-1 family is IL-1 β , a major pro-inflammatory cytokine that initiates inflammation and is essential for the innate host defense against pathogens (Dinarello, 1996). Despite its protective role against pathogenic infection and injury, dysregulation of IL-1 β production leads to aberrant local or systemic inflammation resulting in various auto-inflammatory diseases (Muñoz-Carrillo et al., 2018). Therefore, blockade of IL-1 β activity has been used as a therapeutic strategy to treat different types of auto-inflammatory disorders. So far, three agents for IL-1 β blockade have been approved by the US Food and Drug Administration (FDA) (Dinarello et al., 2012). The first approved drug for IL-1 neutralization is anakinra (Kineret; Amgen) which is a recombinant IL-1 receptor antagonist and prevents the activity of the cytokines IL- α and IL-1 β . Anakinra is approved for the treatment of rheumatoid arthritis and cryopyrin-associated periodic syndromes, like neonatal-onset multisystem inflammatory disease (Mertens and Singh, 2009; Koné-Paut and Galeotti, 2014). The other two drugs available on the market are the soluble decoy receptor, rilonacept (Arcalyst; Regeneron) and the human anti-IL-1 β monoclonal antibody (mAb), canakinumab (Ilaris; Novartis) (Dhimolea, 2010; Dinarello et al., 2012). Rilonacept is also used for the treatment of cryopyrin-associated periodic syndromes and was the first drug to get approval for recurrent pericarditis (Kapur and Bonk, 2009; Schwier, 2021). The mAb canakinumab has been approved to treat systemic juvenile idiopathic arthritis and Still's disease (Orrock and Ilowite, 2016; Sfriso et al., 2020).

In the past years, many studies have investigated the role of the cytokine IL-18, also a member of the IL-1 family. A humanized mAb that blocks IL-18, GSK1070806 (GlaxoSmithKline) has been examined in clinical studies for inflammatory disorders such as inflammatory bowel disease, diabetes mellitus, Crohn's disease, and currently for atopic dermatitis (Vecchié et al., 2021). IL-18 is a pro-inflammatory cytokine and was first recognized for its interferon- γ properties (Okamura et al., 1995). Various hematopoietic and non-hematopoietic cells are able to produce this cytokine; however, the primary producers of IL-18 are macrophages and monocytes following pathogen stimulation, in a similar manner to IL-1 β activation. IL-18 levels rise during viral, bacterial, parasitic and fungal infection and in some cases are correlated with disease severity (Vecchié et al., 2021). For example, the plasma levels of IL-18 can be greater than 1000 pg/ml in Epstein-Barr virus (EBV) and HIV-1 infection (Stylianou et al., 2003; van de Veerdonk et al., 2012) and elevated serum levels were observed during the acute phase of viral hepatitis (Kim et al., 2018). Additionally, significantly increased IL-18 levels were also observed in SARS-CoV-2 infected patients and showed correlation with severity of COVID-19 disease (Satış et al., 2021). These observations led to the idea of IL-18 blockage as a therapeutic option for COVID-19, as well as for other inflammatory disorders (Satış et al., 2021; Vecchié et al., 2021).

Many agents that reduce IL-1 activity are currently in clinical trials to investigate potential treatment of various auto-immune and inflammatory diseases. The two approved drugs, anakinra and canakinumab, are also being investigated as potential treatments for COVID-19; as of now there is inadequate evidence for the treatment of COVID-19 patients with the use of IL-1 blocking agents.

TNF superfamily (TNFSF)

The tumor necrosis factor (TNF) superfamily consists of 19 ligands and 29 receptors. Among those ligands are the well-studied cytokines, TNF- α and TNF- β . Their expression is stimulated primarily by antigen-presenting cells, dendritic cells, B cells and macrophages; however, reports have demonstrated that various cells such as T cells, NK cells, mast cells, basophils, eosinophils, as well endothelial cells express TNF ligands (Cuzzocrea, 2017). The receptors of the TNF superfamily are transmembrane proteins with cysteine-rich motifs in their extracellular domains that bind to their ligands. Interaction between the ligands and receptors of the TNF superfamily induce signals that control cell cycle, proliferation, differentiation, apoptosis and production of inflammatory cytokines and chemokines, and therefore, play a pivotal role in immunity and inflammation (Cuzzocrea, 2017). Various studies have shown that signaling pathways between TNFSF ligands and receptors are active in inflammatory and autoimmune diseases, and thus, TNF-inhibitors have been developed for therapeutic purposes. Five TNF blockers have been approved by the U.S. Food and Drug Administration (FDA) to treat rheumatoid arthritis, psoriatic arthritis, juvenile arthritis, Crohn's disease, ulcerative colitis, ankylosing spondylitis and psoriasis (Table 1).

Table 1 FDA approved agents for cytokine-based therapies.

	Agent	Mechanism of action	Diseases	References
IL-1 agents	Anakinra	Antagonist for IL-1RI; prevents the activity of IL- α and IL-1 β	Rheumatoid arthritis; Cryopyrin-associated periodic syndromes	Mertens and Singh (2009) and Koné-Paut and Galeotti (2014)
	Rilonacept	Soluble decoy receptor, binds to IL-1 β , IL-1 α and IL-1Ra	Cryopyrin-associated periodic syndromes; Recurrent pericarditis	Kapur and Bonk (2009) and Schwier (2021)
	Canakinumab	human anti-IL-1 β monoclonal antibody	Systemic juvenile idiopathic arthritis; Still's disease	Orrock and Ilowite (2016) and Sfriso et al. (2020)
TNF agents	Infliximab	chimeric IgG1 monoclonal Antibody that binds to soluble and transmembrane forms of TNF- α and prevents its activity	Rheumatoid arthritis; Crohn's disease; Ankylosing Spondylitis; Psoriatic arthritis; Plaque psoriasis; Ulcerative colitis	Smolen and Emery (2011)
	Etanercept	TNF inhibitor that acts as a soluble receptor and binds to TNF- α and TNF- β to block their activity	Rheumatoid arthritis; Ankylosing spondylitis; Psoriatic arthritis; Plaque psoriasis; Juvenile idiopathic arthritis	Goldenberg (1999) and Goffe and Cather (2003)
	Adalimumab	recombinant human IgG1 mAb that binds to TNF- α and prevents its activity	Rheumatoid arthritis; Ankylosing spondylitis; Plaque psoriasis; Juvenile idiopathic arthritis; Ulcerative colitis; Hidradenitis suppurativa; Crohn's disease	Bang and Keating (2004), Cassinotti et al. (2008), Salvarani et al. (2012) and Sparrow (2017)
	Certolizumab pegol	PEGylated anti- TNF- α humanized Fab fragment of a mAb that prevents the activity of TNF- α	Rheumatoid arthritis; Psoriatic arthritis; Ankylosing spondylitis; Plaque psoriasis;	Goel and Stephens (2010)

Table 1 (Continued)

	<i>Agent</i>	<i>Mechanism of action</i>	<i>Diseases</i>	<i>References</i>
IL-17 agents	Golimumab	anti-TNF humanized IgG1 κ mAb that neutralizes TNF- α and prevents its activity	Crohn's disease Rheumatoid arthritis; Psoriatic arthritis; Ankylosing spondylitis; Ulcerative colitis	Oldfield and Plosker (2009)
	Secukinumab	human anti-IL-17A IgG1 κ mAb that inhibits IL-17A signaling	Plaque psoriasis; Psoriatic arthritis; Ankylosing spondylitis	Sanford and McKeage (2015)
	Ixekizumab	humanized anti-IL-17A IgG4 mAb that neutralizes IL-17A	Plaque psoriasis; Psoriatic arthritis; Ankylosing spondylitis	Markham (2016)
	Brodalumab	human IgG2 mAb against the IL-17 receptor A	Plaque psoriasis	Pinter et al. (2019)
IL-6 agents	Tocilizumab	anti-IL-6 receptor mAb	Rheumatoid arthritis; Giant cell arteritis; Systemic sclerosis-associated interstitial lung disease; Juvenile idiopathic arthritis; Cytokine release syndrome	Tanaka et al. (2014) and Rubbert-Roth et al. (2018)
IFN agents	Sarilumab	human mAb against IL-6R α	Rheumatoid arthritis	Lamb and Deeks (2018)
	Satralizumab	humanized anti-IL-6 receptor mAb	Neuromyelitis optica spectrum disorder	Heo (2020)
	Siltuximab	chimeric anti-IL-6 mAb	Castleman's disease	Sarosiek et al. (2016)
	Interferon alfa-n3	purified human INF- α that bind to type I INF receptors	Condylomata acuminata	Gall (1995)
	peginterferon alfa-2a	PEGylated recombinant INF- α	Chronic hepatitis C; Chronic hepatitis B	Rajender Reddy et al. (2002) and Matthews and McCoy (2004)
	Interferon alfa-2b	recombinant INF- α	Chronic hepatitis C; Chronic hepatitis B; AIDS-related Kaposi's Sarcoma; Condylomata acuminata	Jaeckel et al. (2001)
	Peginterferon alfa-2b	PEGylated recombinant INF- α	used to treat chronic hepatitis C infection in combination with ribavirin; however, it is no longer recommended due to adverse side-effects	Wirth et al. (2005)
	Interferon beta-1a	recombinant INF- β	Multiple sclerosis	Marziniak and Meuth (2014)
	Peginterferon beta-1a	PEGylated recombinant INF- β	Multiple sclerosis	Hoy (2015)
	Interferon gamma-1b	recombinant INF- γ	Malignant osteoporosis; Chronic granulomatous disease	Todd and Goa (1992) and Lyseng-Williamson (2015)

IL-17 family

The IL-17 family consists of pro-inflammatory cytokines and there are six known ligands within the family (IL1-7A to IL-17F) and five receptors (IL-17RA to IL-17-RE); the ligand IL-17E is also known as IL-25. Various types of immune cells produce IL-17A and IL-17F, while epithelial cell produce IL-17B, IL-17C and IL-17D. IL-17 cytokines show potent pro-inflammatory action that is mainly due to their ability to recruit immune cells and to act synergistically with other pro-inflammatory cytokines, such as TNF, IL-1 β , IFN γ , GM-CSF and IL-22 (Onishi and Gaffen, 2010; Ruiz de Morales et al., 2020). These cytokines play an important role in host defense against extracellular bacteria and fungi; however, many studies have shown their participation in inflammatory and autoimmune disorders, such as psoriasis, atopic dermatitis, psoriatic arthritis, ankylosing spondylitis, and rheumatoid arthritis. A comprehensive review of IL-17 in inflammatory and immune disorders was published recently (Ruiz de Morales et al., 2020).

The most studied member of the family is IL-17A (known as IL-17). IL-17A is produced by Th17, CD8⁺ T cells and ILC3 cells (Langrish et al., 2005), and depending on the tissue type and location of its expression and stimuli, it plays either a protective role against infections, or has harmful pro-inflammatory effects (Pacha et al., 2020). Specifically, it has been shown that this cytokine is involved in various inflammatory and autoimmune diseases. Therefore, blocking IL-17A and IL-17RA has been developed as a strategy for inflammatory disease, resulting three IL-17 inhibitory agents, secukinumab, ixekizumab and brodalumab, have been approved by the U.S. Food and Drug administration (FDA) for the treatment of psoriasis, psoriatic arthritis and ankylosing spondylitis (Table 1).

IL-6 superfamily

The interleukin-6 (IL-6) family consists of 10 ligands that include the cytokines IL-6, IL-11, IL-27, IL-35, IL-39, ciliary neurotrophic factor (CNTF), CLCF, cardiotrophin-1 (CT-1), leukemia inhibitory factor (LIF) and oncostatin M (OSM), and 9 receptors, membrane and soluble IL-6R, IL-11R, IL-27R, IL-12R β 2, IL-23R, CNTFR, LIFR and OSMR (Kang et al., 2020).

They are grouped into one family because they use a common signaling receptor, the subunit glycoprotein 130 kDa (gp130); however, as more members of this family are being discovered, this common characteristic may not be shared in future (Rose-John, 2018). The IL-6 family has redundant and pleiotropic activities, some of the main functions are B-cell stimulation and their differentiation into antibody-producing cells, modulation of T cells, differentiation of T helper type 17 (Th17) cells, hematopoiesis, and cell proliferation (Kang et al., 2020). IL-6 is known to be associated with inflammatory diseases (Kang et al., 2020); for example, elevated IL-6 levels are observed in patients with rheumatoid arthritis. These observations led to the development of the humanized anti-IL-6R antibody, tocilizumab (Actrema, Chugai Pharmaceutical Co.) to block the IL-6 signaling pathway (Tanaka et al., 2014). Tocilizumab has been approved in numerous countries, including the U.S., and is used for the treatment of rheumatoid arthritis, systemic juvenile idiopathic arthritis, and Castleman's disease (Tanaka et al., 2014) (Table 1). To-date, three more IL-6 related therapeutic agents have been approved by the Food and Drug Administration (FDA), sarilumab (Kevzara) also an anti-IL-6R mAb for use in rheumatoid arthritis (Lamb and Deeks, 2018), satralizumab, a second-generation anti-IL-6R mAb for neuromyelitis optica (Heo, 2020) and siltuximab (Sylvant), a recombinant human-mouse chimeric anti-IL-6 mAb for use in patients with multicentric Castleman's disease (Sarosiek et al., 2016) (Table 1).

Increased levels of IL-6 were observed in patients with severe COVID-19 (Blanco-Melo et al., 2020; Price et al., 2020; Ruan et al., 2020) and several reports refer to IL-6 as a key cytokine in COVID-19. During inflammation, monocytes, macrophages and DCs produce IL-6 which activates the JAK/STAT3 pathway. Recent studies have shown the activation of the JAK/STAT3 pathway by IL-6 is associated with the severity of the disease (Giamarellos-Bourboulis et al., 2020; Hirano and Murakami, 2020). Therefore, blockage of IL-6 activity was suggested to be examined for COVID-19 treatment and several clinical studies are now being performed.

Type I cytokine receptor family

The type I cytokine family consists of various types of cytokine receptors and their ligands that include IL-2, IL-3, IL-4, IL-6, IL-7, IL-9, IL-12, IL-15, IL-21; colony stimulating factors (CSFs), like the granulocyte-macrophage colony stimulating factor (GM-CSF). The characteristic of this group is that the cytokine receptors share conserved amino acid sequence motifs, the motifs CCCC and WSXWS (Baker et al., 2007); the receptors also share common subunits (α , β , and γ). The β and γ subunits are involved in signal transduction, whereas the α subunit in interactions between ligand and receptor (Muñoz-Carrillo et al., 2018). For example, IL-2, IL-4, IL-7, IL-9, IL-13, IL-15 and IL-21 share the γ signal transduction subunit and upon ligand binding, activation of the JAK1/JAK3 and STAT 1-5 signaling pathway occurs. Through the β subunit of IL-3, IL-5 and GM-CSF receptors, the JAK/STAT pathway gets activated through interaction with JAK2 (Carson and Kunkel, 2017; Muñoz-Carrillo et al., 2018). Binding to the α subunit does not induce a signaling pathway, but increases the binding affinity between ligand and receptor (Muñoz-Carrillo et al., 2018).

Since various types of cytokines comprise this family, it is reasonable to expect numerous functions, one among many is the modulation and initiation of the inflammatory response (Muñoz-Carrillo et al., 2018).

Type II cytokine receptor family

The type II cytokine superfamily consists of the subfamilies of interferons (IFNs) and IL-10, and like type I superfamily, is categorized based on common characteristics of their receptors. The receptors share the conserved amino acid sequence motif CCCC, but lack the WSXWS motif that is characteristic for the type I cytokine receptor family (Langer et al., 2004). Interferons are best known to induce anti-viral response; as their name suggests, this cytokine subfamily interferes with viral replication (Lee and Ashkar, 2018). Other functions include anti-proliferation and immunomodulation (Platanias, 2005).

This family is divided into three main classes, type I, type II and type III IFN. As a multi-gene cytokine class, the type I IFN class consists of 13 homologous IFN α subtypes, one IFN β and numerous gene products, IFN- δ , IFN- ϵ , IFN- ζ , IFN- κ , IFN- τ and IFN- ω (McNab et al., 2015). The type II class consists of just a single gene product, the IFN γ , while the type III IFN class includes IFN λ 1, IFN λ 2, IFN λ 3 and IFN λ 4 (O'Brien et al., 2014; McNab et al., 2015).

Type I IFNs

Type I IFNs are produced early during an infection and upon binding to their receptor IFNAR, they act through the pathways JAK1 and TYK2 that results in phosphorylation of STAT1 and STAT2 and subsequently to expression of IFN-stimulated genes (Platanias, 2005). These cytokines, mostly IFN α and IFN β , are well-known for their antiviral activity in both virus-infected cells and uninfected, surrounding cells. Through gene transcription, they hinder the viral replication cycle leading to destruction of viral mRNA and inhibition of the viral protein translation (McNab et al., 2015). Moreover, they play an important role in activating the innate immune response through effector cells, such as NK cells (Lee and Ashkar, 2018). An additional function of type I IFN has been reported, where it was shown that these type of cytokines along with IL-12, IL-15 and IL-18 have the ability to induce production of IFN- γ from NK cells (Pegram et al., 2011), and therefore, stimulate antiviral response through the function of IFN- γ . Furthermore, they activate the adaptive immune system for the development of T and B cell responses (Ivashkiv and Donlin, 2014).

Type I IFNs are being used in a wide range of diseases and several drugs have been approved by the FDA. These drugs include a human leukocyte-derived formulation interferon, interferon alfa-n3 (Alferon-N), recombinant proteins, alfa-2a (Roferon-A), interferon alfa-2b (Intron A), interferon beta-1a (Avonex), interferon beta-1a (Rebif), interferon beta-1b (Betaseron), interferon

beta-1b (Extavia), and their pegylated-derivatives for increased plasma half-life, peginterferon alfa-2b (PegIntron, Sylatron), peginterferon alfa-2a (Pegasys) and peginterferon beta-1a (Plegridy) (Vinh, 2014). The IFN- α agents are approved for the treatment of chronic hepatitis C (Rostaing et al., 1998; Rajender Reddy et al., 2002), *molluscum contagiosum* virus (MCV) (Hourihane et al., 1999). IFN- β agents are approved to treat multiple sclerosis (Reder and Feng, 2014) (Table 1).

Type II IFNs

IFN- γ , the only type II IFN member, is primarily produced by NK cells, CD4⁺ T helper cell type 1 (Th1) lymphocytes and CD8⁺ cytotoxic T cells and signals through the IFN- γ receptor (IFNGR) via the JAK1 and JAK2 pathway that leads to phosphorylation of STAT1 (Platanias, 2005). This cytokine plays an essential role in anti-viral responses. Studies showed that in HSV-2 infection in the absence of IFN- γ led to increased virus replication and decreased survival (Ashkar and Rosenthal, 2003; Lee and Ashkar, 2018), also in the context of HCV coinfection in HIV-1 positive patients, the replication of the virus was limited when IFN- γ was present (Kokordelis et al., 2014).

IFN- γ affects the function of surrounding immune cells, mediates interactions between innate and adaptive cells, class-switches B cells, plays an important role in Th1 response by enhancing the antigen presentation process during T cell priming, and increases the expression of major histocompatibility complex (MHC) class I and II. It is also involved in maturation of dendritic cells (Steimle et al., 1994), induces NO production in macrophages, and additionally, promotes complement-mediated phagocytosis through macrophages (Drevets et al., 1996).

Besides its pro-inflammatory functions, IFN- γ limits damaging immune responses that can result in tissue pathology during virus infection. Specifically, studies showed that IFN- γ can suppress the proliferation of type 2 innate lymphoid cells (ILC2) and production of type II cytokines, leading to increased lung pathology (Duerr et al., 2016; Moro et al., 2016; Califano et al., 2018). Association of IFN- γ with disease pathology has also been reported in cases of IFN- γ hyperactivation that results in tissue damage, necrosis and inflammation. Therefore, immune regulatory mechanisms for IFN- γ are considered very important for maintaining the balance between immune response to infection and disease pathology (Kak et al., 2018).

IFN- γ is an important pro-inflammatory cytokine with essential role in host defense against pathogens. Therefore, IFN- γ administration has been shown to be an effective therapeutic strategy to stimulate the immune system and induce an immune response in patients with primary immunodeficiencies (Vinh, 2014). IFN- γ (Actimmune, Horizon Pharma) has been approved for use in patients with malignant osteoporosis and in patients with chronic granulomatous disease (CGD). CGD is an inherited disorder of the phagocyte NADPH oxidase system, and therefore, patients with this disorder are prone to infections. Administration of IFN- γ in CGD patients has been shown to result in a significant protection against infection (Vinh, 2014; Leiding and Holland, 2020). In other cases, IFN- γ has been used to treat active infections, such as salmonellosis, fungal infections, cryptococcal meningitis, and mycobacterial disease (Delsing et al., 2014; Vinh, 2014; Kak et al., 2018) (Table 1).

Type III IFNs (IFN λ s)

Members of the type III INF family are IFN λ -1 (IL-29), IFN λ -2 (IL-28A), IFN λ -3 (IL-28B) and IFN λ 4 (O'Brien et al., 2014; Wack et al., 2015; Zhou et al., 2018). The anti-viral responses of type III IFNs are similar to type I IFNs; they are induced in the early stages of infection when pattern-recognition receptors (PRRs) recognize and bind to pathogen-associated molecular patterns (PAMPs) and upon binding to their receptor IFNLR, they initiate the JAK1 and TYK2 pathway and subsequently to STAT1 and STAT2 phosphorylation, and like type I, they regulate gene expression. The main difference between type I and type III IFNs is that type III IFNs act locally upon viral infection; they target mainly mucosal epithelial cells compared to type I IFNs that act in a wide spectrum of cells and tissues, due to expression of their receptors by a variety of cells (Wack et al., 2015). IL-28R α (a type III IFN receptor) can be found only on macrophages, peripheral blood lymphocytes, dendritic cells and epithelial cells which restricts the cellular response to type III IFNs (Zhou et al., 2018). Despite their restricted activity, this family of cytokines play a crucial role in anti-viral immune responses at epithelial surfaces. When recombinant type III cytokines were used in studies, it was demonstrated that these cytokines are able to restrict replication of numerous viruses, such as Zika virus (ZIKV), vaccinia virus, influenza A virus, influenza B virus, SARS-CoV, human metapneumovirus, respiratory syncytial virus, and HSV-2 (Zhou et al., 2018). Furthermore, some studies have reported that type III IFNs affect the adaptive immune responses. Specifically, it was observed that IFN- λ activity during an adaptive immune response leads to a decrease in Treg activity (Morrow et al., 2009), suggesting that IFN- λ has the ability to enable the adaptive immune response to reduce immunosuppression that is regulated by the Treg cells (Zhou et al., 2018). However, since the discovery of IFN- λ cytokines is relatively recent, further investigations are required to obtain a better understanding of the biology and antiviral activity of those cytokines. The local antiviral activity of the type III INFs can be beneficial for therapeutic development to achieve targeted treatment against viral pathogens.

The future of cytokine therapy

So far, we have shown that cytokines are important in controlling and effecting inflammatory responses, both helpful and deleterious. This has led to early attempts to treat disease by administration of agonist or antagonist molecules. However, this approach is very crude. What has been achieved so far is a description of the cytokine mediated interactions between cells (the wiring diagram) and an understanding of many of the molecular interactions involved. However, the inflammatory response

is a network of nonlinear interactions (Callard et al., 1999). Even simple nonlinear networks can result in complex behavior (Chan et al., 1999). In addition, the timing (kinetics) of signaling pathways will be important, for example the sequence in which cytokine signal can affect the response.

Our attempts so far to modulate cytokine pathways could therefore be compared to interfering in a complex music, for example a jazz concert, in which all the players are listening to each other and playing their instruments at the right volume and timing, resulting in a harmonious effect. Our interventions might be compared to playing a single instrument (such as a trumpet) loudly and all the time. It is perhaps not surprising that the outcome is not always good! What we need to do is to learn how to modulate the tune more subtly. This will involve learning when it is most effective to play our instrument (i.e. administer the agonists and antagonists), and using more than one instrument (give patients different agents at different times) and also listening to the other players in the orchestra (monitoring the tune played by other cytokines, molecules and cells). We also need to think about where the cytokines need to be to have most effect.

We are a long way from achieving this. However, increasing our understanding of the basic science of inflammatory responses is a necessary first step. There can be a temptation, when a particular molecule 'does not work,' to say that the molecule is ineffective. We should perhaps ask first whether we have used it in the right way.

Glossary

CAR-T Technology for treatment of lymphoid malignancies.

CRISPR Technology for precise gene editing.

Epigenetic Reversible modification of gene expression without affecting the DNA sequence.

RNA interference Technology allowing reversible epigenetic gene silencing.

Abbreviations

CAR-T	Chimeric Antigen Receptor T Cell
CRISPR	Clustered Regularly Interspaced Short Palindromic Repeats
miRNA	micro-RNA
RNAi	RNA Interference
saRNA	Self-Amplifying RNA
shRNA	Short Hairpin RNA
siRNA	Small Interfering RNA

Introduction

Gene therapy can be defined narrowly as the replacement of malfunctioning genetic information with functional counterparts for the correction of lack or reduced gene expression activity providing therapeutic effects in animals and humans (Lundstrom, 2015). More broadly, gene silencing based on oligonucleotides (Martinez et al., 2013) and RNA interference (RNAi) (Bobbitt and Rossi, 2016) should be considered as part of gene therapy. Furthermore, both vaccine and immunotherapy approaches aiming at prophylactic and therapeutic efficacy should be accepted as part of modern gene therapy (Ramirez-Montagut, 2015). Chimeric antigen receptor (CAR) T-cell therapy has also demonstrated promises as an alternative approach for gene therapy (Sermer and Brentjens, 2019). Likewise, the application of Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR) has stirred a revolution in gene therapy as unprecedented gene replacement and gene editing have become a reality in vivo (Lino et al., 2018).

Gene therapy entered the scientific community in earnest already in the 1990s and was proclaimed “the medicine of the future” with a major breakthrough in sight. However, in the late 1990s the gene therapy community was hit by some tragic events, which saw withdrawal of funds, support from the pharmaceutical and biotech industries, and halted progress for years. In one case, an 18-year-old patient treated with an adenovirus vector for the non-life threatening disease ornithine transcarbamylase deficiency died mainly due to inadequate execution of clinical protocols (Raper et al., 2003). In another incident, although children with X-linked severe combined immunodeficiency (SCID-X1) were successfully treated by retrovirus-based gene therapy, the integration of the therapeutic retrovirus in the LMO2 proto-oncogene region resulted in development of leukemia in few treated patients (Hacein-Bey-Abina et al., 2008). Since these incidents, major development on aspects of delivery efficacy and safety of gene therapy vectors and improvements of the design and monitoring of clinical trials have restored the confidence in gene therapy. Furthermore, the current COVID-19 pandemic with the demands of urgent development of efficient vaccines against Severe Acute Respiratory

Syndrome-Coronavirus 2 (SARS-CoV-2) has demonstrated the success of genetic engineering in generating viral vector- and nucleic acid-based vaccines (Lundstrom, 2021a).

Today, more than 4000 gene therapy trials have been conducted or are ongoing and several gene therapy-based drugs have been approved (Maldonado et al., 2020). The popularity of gene therapy can be indicated by the 398,859 hits found when searching the PubMed database for “gene therapy.” Although cancer has been the most frequently targeted indication, infectious diseases have also received plenty of attention. Immunity is also an area of importance as it relates to vaccine development as well as immunostimulatory approaches for cancer treatment. The importance of delivery for successful gene therapy is reflected in the presentation of non-viral and viral vectors and their applications for treatment of infectious diseases and immunotherapy of cancer. Vaccine development is described with a special emphasis on targeting the current COVID-19 pandemic. The relatively novel approaches of gene silencing, CAR-T cell technology, and CRISPR are also presented. Finally, an overview is given on approved gene therapy drugs.

Non-viral vector-based gene therapy

Non-viral vectors have been used for various gene therapy applications, especially for vaccine development and cancer immunotherapy (Table 1). DNA vectors provide advantages due to the simplicity of inexpensive and large-scale production and safe application. Recently, mRNA, small interfering RNA (siRNA), and micro-RNA (miRNA) have demonstrated the potential in gene therapy applications (Cullis and Hope, 2017). However, the delivery efficacy has been inferior in comparison to viral vectors. To address this issue, physical methods such as electroporation and gene gun technologies as well as nanoparticle systems have been engineered based on polymers and liposomes. Particularly, cancer immunotherapy has proven attractive for nucleic acid-based therapeutics aiming at overcoming the problems with rapid in vivo degradation, poor uptake in target cells, rapid clearance from circulation, and potential in vivo toxicity (Mukalel et al., 2019). Moreover, the negatively charged DNA is unable to cross the anionic cell membrane unless facilitated by transfection reagents or delivery vehicles (Yin et al., 2014). In the case of DNA delivery, the DNA furthermore has to cross the nuclear membrane. A variety of lipid nanoparticles (LNPs) including liposomes, ionizable lipids, and lipid-polymer NPs have been formulated for cancer therapy (Park, 2002). Liposomes contain polar head groups and non-polar tails and spontaneously self-assemble into vesicles (Malam et al., 2009). Cationic lipids such as DOTMA, DOTPA and zwitterionic DOPE have been commonly used for DNA encapsulation (Bennett et al., 1992) although some toxicity at the administration site (Lv et al., 2006), undesired immune responses (Ma et al., 2005), and clot formation (Senior et al., 1991) have been described. Ionizable LNPs contain fusogenic helper phospholipids (Cheng and Lee, 2016) and cholesterol to increase the stability and membrane fusion (Allen and Cullis, 2013) and lipid-anchored poly(ethylene glycol) (PEG) (Li and Szoka, 2007) to extend the half-life of circulating LNPs. Ionizable LNPs have proven efficient for encapsulation of short synthetic DNA, siRNAs and miRNAs whereas polymer-based NP carriers such as polyplexes (Tolstyka et al., 2016), chitosan-base NPs (Tammam et al., 2015)

Table 1 Examples of gene therapy using non-viral vectors.

Vector	Gene	Response	References
DNA			
pDNA-PLL-NPs	OVA	Cancer vaccine against EG7 tumors	Minigo et al. (2007)
pDNA-PEI	IL-12	Decrease in lung metastases in mice	Jia et al. (2003)
pDNA-PBAE	194-1BBz CAR	Tumor regression in mouse leukemia model	Smith et al. (2017)
CpG-PBAE NPs	STING	Regression in melanoma in mice	Tsai et al. (2018)
pDNA-polymer	TRAIL	60% cell death in UMUC3 and HeLa cells	Goklany et al. (2019)
pDNA-polymer	TRAIL	Tumor regression, prolonged survival in mice	Goklany et al. (2019)
pDNA-BPEI	TRAIL	Bystander effect, efficacy in pancreatic mouse model	Jiang et al. (2018)
pDNA	FASL	Inhibition of lymphocytic infiltration, T cell death	Batteux et al. (1999), Jiang et al. (2020)
pDNA-THL	NPC1	Reduced tissue inclusion bodies in mice	
RNA			
mRNA-LNPs	EPO	Sevenfold increase in mRNA delivery in BALB/c mice	Kauffman et al. (2015)
mRNA-LNPs	TRP2	Tumor regression in B16F10 mice	Oberli et al. (2017)
mRNA-PBAE	Luciferase	Targeted expression in mouse lung after i.v. injection	Kaczmarek et al. (2016)
mRNA-PBAE	GFP	Transfection of dendritic cells in vitro	Su et al. (2011)
mRNA-PBAE	Luciferase	Mucosal tissue delivery after i.n. injection in mice	Su et al. (2011)
mRNA-HDHE	MART1	10-fold reduced tumor volume in B16F10 mice	Mockey et al. (2007)
mRNA-PBAE + Abs	megaTAL	10-fold increase in ex vivo transfection of T-cells	Moffett et al. (2017)
mRNA-LNPs	NY-ESO-1 MAGE-A3	Immune response in melanoma patients in phase I	Kranz et al. (2016)

Abs, antibodies; EPO, erythropoietin; FASL, Fas ligand; HDHE, histidine-rich polylysines mixed with L-histidine-(N,N-di-n-hexadecylamine)ethylamide; IL-12, interleukin-12; i.n., intranasal; i.v., intravenous; MAGE-A3, melanoma associated antigen 3; MART1, melanoma antigen recognized by T-cells; megaTAL, rare cleaving nuclease architecture; NY-ESO-1, New York esophageal squamous cell carcinoma-1; OVA, ovalbumin; pDNA, plasmid DNA; PBAE, poly (β-amino ester); PEI, polyethylenimine; PLL, poly (L-lysine); STING, stimulator of interferon response cGAMP interactor; TRAIL, tumor necrosis factor-related apoptosis-inducing ligand; TRP2, tyrosine-related protein 2.

and poly(beta-amino esters) (PBAEs) (Mangraviti et al., 2015) can condense plasmid DNA into nanoparticles. For instance, poly(L-lysine) (PLL) has been efficiently used for DNA condensation and delivery of PLL-coated polystyrene NPs carrying plasmid DNA encoding ovalbumin (OVA) antigen. PLL NPs have been applied in a model for prophylactic cancer vaccine against EG7 tumor cells (Minigo et al., 2007). Polyethylenimine (PEI) has also been utilized for DNA condensation and aerosol administration of plasmid DNA encoding interleukin-12 (IL-12) resulting in lung-specific IL-12 expression and significantly fewer lung metastases in a murine osteosarcoma lung metastasis model (Jia et al., 2003). Additional polymers such as PBAEs provide tunable biodegradation and poly(β-amino ester) PBAE-based NPs with an anti-CD3e T-cell-targeting antibody has been used for delivery of leukemia-specific CD194-1BBz-CAR plasmid DNA to T-cells in situ in a mouse leukemia model (Smith et al., 2017). Nuclear translocation was facilitated by engineering a microtubule-associated sequence (MTAS) and nuclear localization signal (NLS) peptides in the NPs. Tumor regression was observed in immunized mice. PBAE-based delivery of cyclic dinucleotides (CpG) has demonstrated activation of tumor-specific T-cells and prolonged survival in a mouse melanoma model (Tsai et al., 2018). Plasmid DNA-based delivery has demonstrated promising therapeutic efficacy in preclinical tumor models, which unfortunately did not materialize in efficacy in clinical trials in cancer patients (Zhang et al., 2018a; Yang et al., 2014).

Plasmid DNA-based gene therapy has utilized the expression of apoptotic genes such as the carcinoembryonic antigen (CEA) cell surface glycoprotein involved in regulation of differentiation, apoptosis and cell polarity and urokinase plasminogen activator receptor (UPAR) involved in the degradation of the extracellular matrix (Raocho-Perez et al., 2018). Moreover, apoptosis inducing genes such as tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) (Goklany et al., 2019), Fas ligand (FASL) and BCL2 (Inoue et al., 2016) are potential targets for plasmid DNA based gene therapy. TRAIL preferentially induces apoptosis in cancer cells, but not in normal cells (Goklany et al., 2019). Especially, the transmembrane form of TRAIL expressed from a plasmid DNA encapsulated in aminoglycoside-derived polymers showed 60% cell death in UMUC3 bladder cancer and HeLa cervical cancer cell lines, but did not cause cell death in normal mouse or human fibroblasts. Application of a paromycin-derived polymer significantly reduced tumor burden and increased survival in mice. In another approach plasmid DNA expressing TRAIL encapsulated in branched polyethylenimine (BPEI) showed selective transfection of pancreatic stellate cells (PSCs) with highly expressed fibroblast growth factor receptors (FGFRs) (Jiang et al., 2018). An efficient by-stander effect and tumor cell selective cytotoxicity was observed in vivo. Moreover, therapeutic efficacy was confirmed in a PSC-enriched orthotopic pancreatic tumor model.

In the context of FASL, plasmid DNA-based gene therapy has been evaluated in a mouse model for experimental autoimmune thyroiditis (EAT) (Batteux et al., 1999). Direct injection of plasmid DNA encoding FASL into inflamed thyroid inhibited lymphocytic infiltration of the thyroid and induced death of infiltrating T cells. The lysosomal cholesterol storage disorder Niemann-Pick C1 (NPC1), caused by mutations in the NPC1 gene has been targeted by plasmid DNA-based expression of NPC1 (Jiang et al., 2020). The plasmid DNA encapsulated in pegylated liposomes called Trojan horse liposomes (THLs) were targeted with a monoclonal antibody against the mouse transferrin receptor. Treatment of mice resulted in reduced tissue inclusion bodies in the brain and peripheral organs, but did not provide a prolonged lifespan.

Application of RNA in gene therapy has found renewed interest due to recent development of mRNA vaccines against SARS-CoV-2 (Baden et al., 2021; Polack et al., 2020). Moreover, the use of RNAi (Bobbitt and Rossi, 2016) in the form of short hairpin RNA (shRNA), small interfering RNA (siRNA) and micro RNA (miRNA) has significantly broadened the application range in gene therapy (Cullis and Hope, 2017). Due to the sensitivity of RNA to degradation, various NP platforms have been applied for RNA delivery. In this context, LNPs consisting of ionizable lipids, phospholipids, cholesterol and polyethylene glycol (PEG) have been utilized for systemic delivery of luciferase and erythropoietin mRNA in BALB/c mice (Kauffman et al., 2015). The LNPs provided a sevenfold increase in mRNA delivery. However, siRNA delivery was not improved indicating differences in optimized formulation requirements for mRNA and siRNA. In another study, multilamellar ionizable LNPs were able to transfect neutrophils, macrophages and dendritic cells resulting in efficient delivery of tyrosine-related protein 2 (TRP2) mRNA and reduction of tumor volume in a B16F10 mouse tumor model (Oberli et al., 2017). PBAE-based LNPs loaded with luciferase mRNA generated near-exclusive expression in mouse lung after intravenous administration (Kaczmarek et al., 2016). Moreover, using the same approach, GFP mRNA was successfully delivered to dendritic cells in vitro and luciferase mRNA to mucosal tissue compartments after intranasal administration (Su et al., 2011). PEGylated histidine-rich polylysines mixed with L-histidine-(N,N-di-n-hexadecylamine)ethylamide (HDHE) and cholesterol liposomes applied for delivery of the melanoma antigen MART1 mRNA to T-cells resulted in a 10-fold reduction in tumor volume and a 75% decrease in detectable lung metastases in a B16F10 mouse melanoma model (Mockey et al., 2007). Furthermore, coating of PBAE NPs with CD3 and CD8 antibodies for T-cell targeting provided an additional 10-fold ex vivo transfection of T-cells (Moffett et al., 2017). LNPs complexed with NY-ESO-1, MAGE-A3, tyrosinase and TPTE mRNA have been evaluated in a phase I dose-escalation clinical trial, which showed that neutral or negatively charged LNP-mRNA complexes were well tolerated and generated dose-dependent IFN- and antigen-specific T-cell responses in melanoma patients (Kranz et al., 2016).

Viral vector-based gene therapy

The superior delivery properties of viral vectors have made them attractive vehicles for gene therapy applications. The large spectrum of viral vectors with different properties allows for choosing each vector for each application. Needless to say, there is no universal vector that can be utilized for all types of gene therapy applications. The basic criteria relate to the therapeutic needs, which will have a major input on vector choice. Depending on whether the therapy targets chronic or acute diseases, clearly dictates the need for

long-term or transient expression. In this context, the ability of the viral vector to remain episomal or integrate in the host genome plays a fundamental role. Obviously, replication-deficient vectors, especially vectors based on single-stranded RNA viruses, usually generate short-term high level expression and although the safety levels have been improved with specific chromosomal integration it is still a factor to take into account. Moreover, oncolytic viral vectors, which replicate in tumor cells but not normal cells have proven useful for cancer therapy (Reis and Korn, 2002). Viral vectors have been applied for a large variety of indications including cancer, cardiovascular, infectious, hematologic, lung, metabolic, muscular, neurologic, and ophthalmologic diseases (Lundstrom, 2021b). Numerous different virus species such as adenoviruses, adeno-associated viruses (AAV), alphaviruses, flaviviruses, measles virus, rhabdoviruses, herpes viruses, retroviruses, lentiviruses, Newcastle disease virus, reoviruses, poxviruses, picornaviruses, and polyomaviruses have been engineered. These virus species comprise of DNA (single- and double-stranded) and single-stranded RNA viruses. Due to the large number of gene therapy applications with various viral vectors makes it only possible in this review to present examples with emphasis on infectious diseases and cancer immunotherapy (Table 2).

As the majority of gene therapy applications for infectious diseases are based on immunization with viral vectors expressing surface proteins of viral, bacterial or parasite pathogens for inducing antigen-specific immune responses and protection against pathogen challenges, they are presented in the section on vaccine development. However, a number of applications in cancer therapy has aimed at tumor growth inhibition and tumor regression in animal models with the goal of tumor eradication, prolonged survival and even cure (Lundstrom, 2015). In this context, pancreatic cancer cells were targeted by engineering an oncolytic adenovirus vector with the tumor cell-specific SYENFSA (SYE) ligand, which resulted in efficient oncolysis of pancreatic ductal adenocarcinoma (PDAC) cells (Nagasato et al., 2017). Moreover, high transduction efficiency of pancreatic neuroendocrine tumors was obtained by introduction of a survivin promoter in the adenovirus vector leading to complete tumor regression in BALB/c mice. Moreover a chimeric adenovirus vector (Ad5/3) engineered with the melanoma differentiation associated gene-7 (MDA-7) and interleukin-24 (IL-24) for simultaneous replication in cancer cells and secretion of IL-24 showed in preclinical animal models selective tumor killing and bystander activity (Emdad et al., 2018). Moreover, encapsulation of Ad5/3 in microbubbles allowed “stealth delivery” to tumors. In the context of alphaviruses, intravenous administration of 3×10^7 pfu of the oncolytic M1 virus resulted in selective killing of zinc-finger antiviral protein (ZAP)-deficient cancer cells in mice implanted with mammary carcinoma of B16 melanoma cells (Lin et al., 2014). In another approach a Kunjin virus (KUN) vector expressing the granulocyte macrophage-colony stimulating factor (GM-CSF) was intratumorally administered to mice with CT26 colon xenografts (Hoang-Le et al., 2009). The therapy resulted in the cure of over half of the treated animals with no tumor occurrence for 18 months. Moreover, intratumoral injection of KUN-GM-CSF in B16-OVA melanoma bearing mice significantly reduced tumors and provided a cure rate of 67% (Hoang-Le et al., 2009).

Oncolytic herpes simplex virus (HSV) can provide highly efficient replication in tumor cells, which has generated significant reduction in tumor growth and prolonged survival in mice with implanted breast tumors (Eissa et al., 2017). The oncolytic HSFV HF10 vector has been subjected to a dose-escalation phase I clinical trial in 17 Japanese patients of which 6 had recurrent breast cancer, 3 had recurrent head-and-neck cancer and 8 were diagnosed with nonresectable pancreatic cancer (Kasuya et al., 2014). The treatment was safe with no adverse events. Based on pathological findings, tumor markers and diagnostic radiography some therapeutic effects were registered. Moreover, patients with nonresectable locally advanced pancreatic cancer were intratumorally administered the oncolytic HSV HF10 vector (Hirooka et al., 2018). The outcome was partial response (PR) in three patients, stable disease (SD) in four patients, and progressive disease (PD) in nine patients. Preliminary results from a phase II study on combination therapy with HSFV HF10 and the anti-CTLA-4 (ipilimumab) monoclonal antibody in patients with nonresectable or metastatic melanoma indicated good safety and antitumor activity (Eissa et al., 2017). The treatment resulted in prolonged long-term survival in immune-competent mice.

The nonlytic amphotropic retroviral replicating vector (RRV) Toca 51 expressing the yeast cytosine deaminase (CD) was subjected to intravenous and intracranial administration in an orthotopic glioma model (Huang et al., 2015). The Toca 51 vector was further subjected to an open-label, dose-escalation, phase I trial in patients with recurrent or progressive high-grade glioma (HGG) (Cloughesy, 2016). The overall survival of 13.6 months was superior to the control group. Highly encouraging preliminary results of therapeutic efficacy have also been obtained in a phase II/III clinical trial with Toca 511 in glioma patients (Inoko et al., 2018).

Due to its oncolytic activity Newcastle disease virus (NDV) is an attractive vector for cancer therapy (Niu et al., 2015). NDV-based expression of IL-12 and IL-15 has provided suppression of tumor growth in a mouse melanoma model. Reverse genetics has been applied to engineer the oncolytic NDV D90 strain expressing GFP, which demonstrated suppression of tumor growth in athymic mice with lung tumors (Chai et al., 2014). It was also demonstrated that the combination of NDV-based expression of TRAIL and IL-2 showed superior apoptotic activity and tumor regression in mice than administration of either NDV-TRAIL or NDV-IL-2 alone (Bai et al., 2014). Similarly, superior survival was observed in hepatocellular carcinoma and melanoma mouse models with the NDV-IL-2-TRAIL combination. In the context of clinical trials, 1.2×10^{10} and 1.2×10^{11} pfu/m² of the NDV PV101 strain were administered to 79 patients with solid tumors in a phase II study (Pecora et al., 2002). The treatment resulted in objective responses and progression-free survival ranging from 4 to 31 months. Furthermore, NDV-based immunotherapy showed prolonged survival and short-term improvement of quality of life in 335 colorectal cancer patients in a phase III trial (Liang et al., 2003).

Measles viruses (MVs) have been applied for expression of the sodium iodide symporter (NIS) showing enhanced tumor killing in mice with anaplastic thyroid cancer (ATC) (Reddi et al., 2012). MV-based expression of the super-cytosine deaminase (SCD) comprising the bifunctional cytosine deaminase and uracil phosphoribosyltransferase resulted in killing of human ovarian cancer

Oncolytic reovirus	Breast cancer	Reduced tumor burden, prolonged survival	Mostafa et al. (2018)
Oncol. reovirus + anti-PD	Breast cancer	Superior therapeutic efficacy in mice	

Ad, adenovirus; *ATC*, anaplastic thyroid cancer; *CA*, carcinoma; *CD*, cytosine deaminase; *CEA*, carcinoembryonic antigen; *CPVX*, Cowpox virus; *CTCL*, cutaneous T-cell lymphoma; *CTL*, cytotoxic T-lymphocyte; *DAF*, decay-accelerating factor; *DOX*, doxorubicin hydrochloride; *FCU1*, fusion suicide gene 1; *GM-CSF*, granulocyte macrophage-colony stimulating factor; *HCC*, hepatocellular carcinoma; *HSV*, herpes simplex virus; *ICAM-1*, intercellular adhesion molecule-1; *IFN- β* , interferon- β ; *IL-24*, interleukin-24; *KUN*, Kunjin virus; *MDA-7*, melanoma differentiation associated gene 7; *MUC1*, mucin 1; *NIS*, sodium iodide symporter; *PANVAC TRICOM*, vaccinia and fowl pox virus system; *PDAC*, pancreatic ductal adenocarcinoma; *PR*, partial response; *RRV*, retroviral replicating virus; *s.c.*, subcutaneous; *SCD*, super cytosine deaminase; *SD*, stable disease; *TRAIL*, tumor necrosis factor-related apoptosis-inducing ligand; *VSV*, vesicular stomatitis virus.

cell lines and primary tumors (Hartkopf et al., 2013). Administration of MV-SCD in mice with hepatocellular carcinoma xenografts resulted in long-term virus replication in tumor tissue and induced apoptotic-like cell death (Lampe et al., 2013). Additionally, MV-SCD delivery to mice with human cholangiocarcinoma (huCCT1) xenografts provided tumor regression and prolonged survival (Lange et al., 2013). In the context of clinical trials, the MV-Edm-Zagreb strain was subjected to a phase I study in patients with cutaneous T-cell lymphoma (CTCL) (Heinzerling et al., 2005). The treatment was safe with no dose-limiting toxicity and in one patient complete regression was detected in one CTCL tumor and partial regression was observed in four out of five CTCL tumors. Moreover, 10^7 – 10^9 MV-CEA particles were administered to recurrent ovarian cancer patients in a phase I/II clinical trial (Galanis et al., 2010). The MV-CEA treatment caused no dose-limiting toxicity. However, doses of 10^7 – 10^9 MV-CEA particles showed better efficacy resulting in SD in nine out of nine patients and the median overall survival of 12.15 months was twice as long as expected.

Oncolytic rhabdoviruses such as vesicular stomatitis virus (VSV) expressing interferon- β (IFN- β) and NIS have demonstrated dose-dependent tumor regression in 5TGM1 plasmacytoma tumor bearing mice (Zhang et al., 2016). In another study, intravenous administration of VSV-IFN- β -NIS in purpose-bred dogs with naturally occurring tumors showed a maximum tolerated dose (MTD) of 10^{10} TCID₅₀ and only mild-to-moderate adverse events (LeBlanc et al., 2013). Moreover, nine dogs with various malignancies were subjected to a single intravenous injection of VSV-IFN- β -NIS (Naik et al., 2018). Rapid but transient remission of high-grade peripheral T-cell lymphoma was observed in two dogs. VSV-based expression of human mucin 1 (MUC1) provided significant reduction in PDAC tumor growth in mice (Hastie and Grdzelskivili, 2012).

The family of small RNA viruses, Picornaviruses, have been subjected to cancer gene therapy. A single subcutaneous injection of the Coxsackievirus A21 (CAV21) carrying the intercellular adhesion molecule-1 (ICAM-1) and decay-accelerating factor (DAF) genes resulted in reduced tumor burden and efficient tumor regression in SCID mice with implanted melanoma tumors (Shafren et al., 2014). Moreover, SCID mice with implanted T47D and MDA-MB-231-luc breast tumor xenografts subjected to intravenous administration of CAV21-ICAM-1-DAF showed significant regression of pre-established tumors and eradication of metastases (Skelding et al., 2009). Superior tumor regression was achieved by combination therapy of CAV21-ICAM-1-DAF and peritoneal doxorubicin hydrochloride in a mouse breast tumor model (Skelding et al., 2012).

Poxviruses have been commonly used for cancer gene therapy (Al Yaghchi et al., 2015). For example, recombinant vaccinia and fowl pox viruses expressing the MUC1 and CEA genes, respectively, comprise the PANVAC system (Madan et al., 2007). Engineering of the PANVAC TRICOM system with the cluster of differentiation B7.1, ICAM-1 and the leukocyte function-associated antigen-3 (LFA-3) generated MUC1 and CEA cytotoxic T-lymphocyte (CTL) responses in mice. Moreover, in mice implanted with hepatocellular carcinoma (HCC) the GLV-2b372 vaccinia virus showed a 50% decrease in tumor volume compared to a 400% increase for mice injected with placebo (Ady et al., 2015). The GLV-1 h153 vaccinia virus expressing the NIS gene provided synergistic effect in the context of tumor growth and survival in a transgenic adenocarcinoma of the mouse prostate (TRAMP) model in combination with radioiodide treatment (Mansfield et al., 2016). In another approach, systemic administration of the cowpox virus (CPVX) expressing the fusion suicide gene (FCU1) showed inhibition of tumor growth in U-87-MG glioblastoma and LoVo colon cancer mouse models (Ricordel et al., 2017). In the context of clinical trials, the PANVAC-VF vector has been subjected to a phase III clinical trial in patients with unresectable stage III-IV melanoma resulting in more than 50% reduced tumor size in 64% of injected tumors (Riedmann, 2014). Moreover, due to a bystander effect tumor regression in one-third of un-injected tumors was detected.

Finally, oncolytic reoviruses present an attractive alternative for cancer therapy due to the susceptibility of pancreatic cell lines such as Panc1 and BxPC3 (Etoh et al., 2003). Intratumoral administration of reovirus vectors to mice with implanted Panc1 and BxPC3 xenografts suppressed tumor growth and demonstrated systemic antitumor responses. Moreover, reovirus administration has shown significantly reduced tumor burden and prolonged survival in a syngeneic mouse EMT6 breast tumor model (Mostafa et al., 2018). Superior therapeutic efficacy was achieved by combination therapy of reovirus and the checkpoint inhibitor anti-PD1 antibody.

Vaccine development

Although vaccines are not considered as gene therapy at its purest application, it is worth to include a summary here, especially in the light of the current COVID-19 pandemic. A large number of viral vectors have been applied for vaccine development targeting infectious diseases including vaccines against viral, bacterial and parasite pathogens. Examples of different applications are given below and listed in Table 3.

The annual influenza virus outbreaks have underlined the importance of developing efficient vaccines based on genetic engineering as attractive alternatives to classic vaccines based on inactivated viruses (Lundstrom, 2019). In this context, the Ad5 vector expressing the codon-optimized hemagglutinin (HA) gene from the influenza virus strain A/Vietnam/1203/2004(H5N1) provided complete protection of immunized mice against challenges with lethal doses of virus (Gao et al., 2006). A single injection of Ad5-HA protected chicken from influenza virus challenges. In another approach the Venezuelan equine encephalitis virus (VEE) expressing the HA gene from the Hong Kong influenza virus isolate A/HK/156/97 was administered to chicken resulting in protection against influenza virus challenges (Schultz-Cherry et al., 2000). Moreover, Semliki Forest virus (SFV) particles expressing the HA and nucleoprotein (NP) genes provided protection against influenza virus challenges in mice (Fleaton et al., 2001).

Another important target for vaccine development comprise HIV (Poluri et al., 2003) for which an AAV-vector expressing the HIV-1 Gag elicited HIV-specific T- and B-cell responses (Lin et al., 2008). Moreover, a vaccinia virus-based system was utilized for the expression of a chimeric antigen comprising the HIV-1 Env and GM-CSF genes, which elicited strong HIV-specific cellular

AAV, adeno-associated virus; Ad, adenovirus; CS epitope, *Plasmodium yoelii* circumsporozoite protein; EBOV, Ebola virus; E & ER, T-cell epitopes and ER-targeting signal; GP, glycoprotein; HA, hemagglutinin; HIV, human immunodeficiency virus; IF3, translation initiation factor 3; NP, nucleoprotein; PA, *Bacillus anthracis* protective antigen; SFV, Semliki Forest virus; SIN, Sindbis virus; VEE, Venezuelan equine encephalitis virus; VV, vaccinia virus.

immune response in BALB/c mice (Rodr Guez et al., 1999). In another approach, a rabies virus (RABV) vector expressing the HIV-1 gp160 gene elicited solid and long-lasting memory CTL responses in immunized mice (McGettigan et al., 2001). SFV-based expression of HIV-1 Env/Gag/polRT either in combination or individually demonstrated strong antigen-specific T-cell responses in immunized mice (Ajbani et al., 2017). In the context of clinical trials, healthy HIV-negative volunteers received subcutaneous administration of VEE particles expressing the non-myristoylated form of HIV-Gag in a phase I study (Wecker et al., 2012). The treatment was safe and tolerable, but elicited only modest immune and T-cell responses. In another study, an Ad5 vector expressing HIV Gag-Pol-Nef generated HIV-1 specific T cells in healthy volunteers although providing limited HIV-1 inhibition (Hayes et al., 2016).

Although the recombinant vaccines Gardasil and later Gardasil 9 have been approved against human papilloma virus (HPV) (Gupta et al., 2016), there has been a genuine interest in developing viral vector-based HPV vaccines. In this context, Ad5 Copenhagen strain was used for expression of the HPV-16 oncoproteins E6 and E7 showing protection against tumors in BALB/c or C57B1/6 mice (He et al., 2000). Replicon-based alphavirus vectors have been applied as DNA-based vaccines against HPV (van de Wall et al., 2018). Conventional plasmid DNA-based vaccines were unable to prevent tumor outgrowth, while the DNA replicon vaccine managed to provide therapeutic efficacy and rendered 85% of immunized mice tumor-free. Moreover, recombinant SFV particles expressing the HPV E6 and E7 fused to T-cell epitopes and an ER-targeting signal generated tumor regression and protection in mice (Ip et al., 2015). The first-in-human phase I with SFV particles expressing HPV E6 and E7 was conducted in 12 patients with a history of cervical intraepithelial neoplasia (Komdeur et al., 2021). The study demonstrated good safety and induced immune responses in all participants.

Ebola virus (EBOV) have seen strong vaccine development activity due to recent outbreaks in Africa. For instance, C57BL/6 mice immunized with VEE particles EBOV nucleoprotein (EBOV-NP) were protected against challenges with lethal doses of EBOV (Wilson and Hart, 2001). Moreover, a single immunization of BALB/c mice and guinea pigs with VEE-EBOV glycoprotein (GP) or a combination of VEE-EBOV-GP and VEE-EBOV-NP particles protected animals from EBOV challenges (Pushko et al., 2000). However, immunization with only VEE-EBOV-NP provided protection to mice but not to guinea pigs. In another approach, VSV vectors expressing the EBOV-GP provided protection against the West African EBOV-Makona strain in rhesus macaques (Marzi et al., 2015). Similarly, immunization with VSV-EBOV-GP and VSV expressing Marburg virus (MARV) GP protected non-human primates against EBOV and MARV, respectively (Geisbert and Feldmann, 2011). Related to clinical evaluation, the VSV-EBOV-GP particles (based on the Zaire strain named VSV-ZEBOV) were subjected to a phase III clinical trial in 4123 individuals with suspected Ebola virus disease (EVD) (Henao-Restrepo et al., 2015). An additional 3528 persons were subjected to a delayed vaccination. No EVD was recorded in the immediate vaccination group, whereas 16 cases of EVD were detected in the delayed vaccination group. Similarly, substantial protection was achieved in another phase III trial with the VSV-ZEBOV vaccine candidate in Guinea and Sierra Leone (Henao-Restrepo et al., 2017).

Vaccine development against the SARS-CoV-2 has obviously been the biggest and fastest bioscience initiative in history and the results have been reported in detail on many occasions, so it is justified to give only a short summary here. Viral vectors have played a central role in COVID-19 vaccine development in parallel with approaches based on inactivated virus, protein subunits and nucleic acids (Lundstrom, 2021a). Ad vectors have played a key role in COVID-19 vaccine development. The ChAdOx1 nCoV-19 vaccine candidate is based on the simian Ad-virus ChAdOx1, which has been engineered to express the full-length SARS-CoV-2 spike (S) protein, showing strong immunogenicity and protection against SARS-CoV-2 challenges in mice and rhesus macaques (van Doremalen et al., 2020). In phase III clinical evaluation, the ChAdOx1 nCoV-19 vaccine showed good safety and 62.1% efficacy after vaccination with two doses of 5×10^{10} Ad particles and 90.0% efficacy after a lower first dose of 2.2×10^{10} Ad particles followed by the standard dose for the second immunization (Voysey et al., 2021). In another approach, the Ad5 vector expressing the codon-optimized SARS-CoV-2 S protein (Ad5-S-nb2) elicited systemic and cell-mediated immune responses and provided protection against SARS-CoV-2 challenges in rhesus macaques (Feng et al., 2020). Moreover, robust T-cell and humoral immune responses were demonstrated after intramuscular Ad5-S-nb2 administration in phase I (Zhu et al., 2020a) and phase II studies (Zhu et al., 2020b). The full-length SARS-CoV-2 S protein has also been introduced into an Ad26 vector, which in contrast to previous Ad-based approaches required a single immunization to protect hamsters against SARS-CoV-2-related pneumonia (Tostanoski et al., 2020). Moreover, strong immune responses were detected after a single intramuscular administration of Ad26.COVS.2 in healthy volunteers in a phase I/II clinical trial (Sadoff et al., 2021). In another Ad-based approach, the strategy of using two different Ad serotypes to prevent immune reactions against pre-existing Ad, the Ad26 and Ad5 serotypes expressing the SARS-CoV-2 S protein (rAd26-S/rAd5-S) were administered sequentially. The rAd26-S/rAd5-S regimen elicited strong immune responses in animal models and showed good safety and robust immune responses in a phase I/II clinical trial (Logunov et al., 2020). Interim results from a phase III demonstrated good tolerability and 91.6% vaccine efficacy (Logunov et al., 2021). In addition to Ad vectors, COVID-19 vaccine candidates based on measles virus, VSV, modified vaccinia Ankara (MVA) virus, lentiviruses and influenza virus are under development and have been described in more detail elsewhere (Lundstrom, 2021a).

Although not as commonly targeted, vaccine development for bacterial infections has been addressed for viral vectors. For example, Sindbis virus (SIN), a self-replicating RNA alphavirus, has been utilized for expression of the protective antigen (PA) of *Bacillus anthracis* (Thomas et al., 2009). Immunization of Swiss Webster mice with SIN-PA particles elicited PA-specific IgG and neutralizing antibodies and provided protection against challenges with the lethal Ames strain. In another approach, immunization of BALB/c mice with recombinant SFV particles expressing the *Brucella abortus* translation initiation factor 3 (IF3) elicited immune responses and demonstrated protection against challenges with the virulent *B. abortus* 2308 strain (Cabrera et al., 2009).

In the context of parasites, SFV particles carrying the *Plasmodium falciparum* Pf332 antigen have been administered to BALB/c mice (Andersson et al., 2001). Immunization elicited Th1-type immune responses and generated immunological memory. The efficacy of the immune response was enhanced by booster immunization. In another study, SIN particles expressing the class I major histocompatibility complex-restricted-9-mer epitope SYVPSAEQI of the *P. yoelii* circumsporozoite (CS) protein (SIN-Mal) were subcutaneously injected into BALB/c mice (Tsuji et al., 1998). The immunization induced strong epitope-specific CD8⁺ T-cell responses and provided protection to a high degree against malaria. Recently, an SFV vector has been engineered for the expression of the *Leishmania major* stress inducible protein 1 (LmSTI1) and *Phlebotomus papatasi* SP15 (PpSP15) as a fusion protein (Sadat Savar et al., 2021). High levels of SFV-based expression of the PpSP15-LmSTI1 fusion protein was detected in BHK-21 cells and immunization studies in mice are in progress.

Gene silencing

RNAi has been introduced as a therapeutic using different viral vectors such as Ad (Wang et al., 2017), AAV (Schaar et al., 2017) and retroviruses (Devroe and Silver, 2004). Conditionally replicating lentivirus vectors (Westerhout et al., 2006) and self-replicating rhabdoviruses (Bastin et al., 2018) and alphaviruses (Ylösmäki et al., 2013) have also been employed for RNAi-based gene silencing. Examples of viral vector-based gene silencing are described below and summarized in Table 4.

Ad vectors have been applied for gene silencing of the mosquito-borne Tembusu virus (TMUV) by expression of shRNAs against the TMUV E and NS5 genes (Wang et al., 2017). Both RNA replication and TMUV production was efficiently downregulated in Vero

AAV, adeno-associated virus; Ad, adenovirus; amiRs, artificial microRNAs; HBV, hepatitis B virus; HD, Helper dependent; HIV, human immunodeficiency virus; MMLV, Moloney murine leukemia virus; pri-miRs, primary microRNAs; S, spike protein; SARS-CoV, Severe Acute Respiratory Syndrome-Coronavirus; scAAV, self-complementary AAV; shRNA, Small hairpin RNA; siRNA, small interfering RNA; TMUV, Tembusu virus.

cells, which was dose-dependent and lasted for at least 96 h. Moreover, helper-dependent Ad vectors have been applied for inhibition of hepatitis B virus (HBV) replication by delivery of artificial antiviral pri-miRNAs (Mowa et al., 2012). Ad-specific pri-miRNAs introduced into an Ad vector with a CMV promoter showed efficient inhibition of HBV replication. Replacement of the CMV promoter with the liver-specific murine transthyretin (MTTR) promoter enhanced the inhibition of HBV replication to 94% in mice lasting for 5 weeks (Mowa et al., 2012). In another study, AAV-based delivery of HBV-targeted shRNAs showed profound reduction of HBV titers in transgenic mice (Chen et al., 2009). The problem of pre-existing antibodies against AAV was demonstrated by lack of anti-HBV RNAi activity after readministration of the AAV8-HBV-shRNA vector, whereas AAV7 and AAV9 provided prolonged anti-HBV effect. Moreover, self-complementary AAV (scAAV) vectors, which can fold into double-stranded DNA without requiring DNA synthesis (McCarthy, 2008), were applied for gene silencing by mono- and tri-meric artificial pri-miRs derived from pri-miR-31 (Maepa et al., 2017). Placing the scAAV-HBV-pri-miRs under the control of the liver-specific MTTR promoter generated significant suppression of HBV replication for at least 32 weeks in mice.

Ad was targeted as it can cause life-threatening conditions in immunocompromised individuals (Schaar et al., 2017). The scAAV vectors package an inverted repeat genome. Efficient inhibition of Ad5 replication was achieved in vitro by delivery of two scAAV9 vectors carrying three copies of artificial miRNA against the Ad5 pTP (amiR-pTP) gene and three copies against the Ad5 E1 (amiR-E1A) gene, respectively. Administration of scAAV9 to immunosuppressed Syrian hamsters resulted in two order of magnitude reduction of Ad5 levels and reduced damage to the liver (Schaar et al., 2017).

Retrovirus vectors have also been applied for gene silencing. In this context, the Moloney murine leukemia virus (MMLV) was demonstrated to provide safe delivery of anti-HIV tat ribozyme in a phase I clinical trial in HIV-1 infected adults (Macpherson et al., 2005). In another phase I study, the MMLV vector expressing an anti-HIV ribozyme was delivered to mature hematopoietic cells in HIV patients (Amado et al., 2004). Even patients with multidrug-resistant infections vector-containing mature myeloid and T lymphoid cells were detected. In a phase II trial, an MMLV-based vector was applied for tat-vpr specific anti-HIV ribozyme delivery showing good safety, biologic ribozyme activity, but no statistically significant difference in viral load compared to placebo (Mitsuyasu et al., 2009). Lentivirus vectors have also been designed for antiviral shRNA expression (Westerhout et al., 2006). A conditionally replicating doxycycline (dox)-dependent HIV-1 vector was engineered where dox withdrawal prevented transcription of the integrated provirus, but allowed the shRNAs to inhibit the HIV-1 replication (Westerhout et al., 2006). A combinatorial replication-deficient lentivirus vectors expressing a U6 Pol III promoter-driven shRNA targeting HIV-1 rev and tat mRNAs, a U6 nuclear localization TAR RNA decoy and a VA1-derived Pol III cassette expressing an anti-CCR5 ribozyme was engineered (Li et al., 2005b). Transduction of CD34⁺ hematopoietic progenitor cells resulted in superior inhibition of HIV replication after combination therapy compared to treatment with individual shRNAs. Furthermore, transduction of peripheral blood-derived CD34⁺ hematopoietic cells, which were transplanted and successfully engrafted into four AIDS patients resulted in shRNA and ribozyme expression for at least 24 months (DiGiusto et al., 2010).

In the context of coronaviruses, there has been several speculative reviews on RNAi-based therapy targeting SARS-CoV-2 (Uludag et al., 2020; Donia and Bokhari, 2021). So far, only computational design of siRNAs for SARS-CoV-2 have been reported (Zhao et al., 2020). However, experimental data is available for SARS-CoV. For example, siRNAs targeting the S1 and S2 regions of the S protein efficiently inhibited SARS-CoV replication in Vero E6 cells (Zhang et al., 2004). Moreover, four chemically synthesized siRNAs targeting S, NSP12, NSP13 and NSP16 inhibited SARS-CoV replication in FRhK4 fetal rhesus kidney cells (Zheng et al., 2004). The siRNAs targeting the S and NSP12 suppressed SARS symptoms in rhesus macaques (Li et al., 2005a).

CAR T-cell technology

The chimeric antigen receptor (CAR) T-cell technology has revolutionized the treatment of lymphoid diseases, particularly diffuse large B-cell lymphoma (DLBCL) and acute lymphoblastic leukemia (ALL) (Sermer and Brentjens, 2019). As CARs are recombinant receptors, they can provide both antigen-binding and T-cell activation (Sadelain et al., 2013). CARs can target cell surface tumor antigens and in the second generation CARs tri-partite receptors with costimulatory domains have been engineered. Combination of costimulatory ligands, chimeric costimulatory receptors and cytokines has enhanced T-cell potency, specificity and safety in patients. Application of CAR T-cell technology has successfully reduced the remission rates for hematologic cancers up to 80% (Mohanty et al., 2019). In particular, encouraging results have been obtained for the treatment of ALL in children and young adults and in adults with DLBCL (Pehlivan et al., 2018). Anti-CD19 CAR T-cell therapy has also been successfully used for treatment of B-cell non-Hodgkin lymphoma (Abramson, 2020). Furthermore, in a phase I CAR T study targeting the B-cell maturation antigen (BCMA) all patients with relapsed or refractory multiple myeloma showed partial or better responses (Raje et al., 2019).

In addition to targeting CD19 for relapsed or refractory pre-B acute lymphoblastic leukemia (B-ALL) a CD22-targeted CAR (CD22-CAR) was subjected to a phase I trial in children and adults (Fry et al., 2018). The outcome of the study was clinical activity in leukemia cases resistant to anti-CD19 immunotherapy and demonstration of potency against B-ALL comparable to CD19-CAR treatment. In another approach, to address relapses occurring for CD19 disease, bispecific anti-CD20, anti-CD19 (LV20,19) CAR T-cell therapy was applied for a first-in-human phase I study on relapsed and refractory B cell malignancies (Shah et al., 2020). Results from bispecific CAR treatment of adult patients with B cell non-Hodgkin lymphoma or chronic lymphocytic leukemia (CLL) demonstrated good safety, low toxicity and high efficacy. In a novel approach a novel CAR including both a single-chain variable fragment (scFv)-BCMA and an scFv-CD19 was engineered in tandem orientation (tan-CAR) to be able to target both BCMA and CD19 expressed on multiple myeloma cells (Kang et al., 2020). The tan-CAR T cells promoted significant anti-tumor activity against both BCMA and CD19 in tumor cells both in vitro and in vivo. Related to the B cell aplasia caused by "on-target off-tumor" toxicity associated with CD19-CAR T therapy, an inhibitory CAR (iCAR) was incorporated (Tao et al., 2020). The KIR/PD-1 inhibitory CAR (iKP CAR) was engineered by fusion of the extracellular domain of the killer cell immunoglobulin-like receptor 2DL2 (KIR2DL2) with the intracellular domain of PD-1. The iKP CAR showed strong cytotoxicity in vitro and anti-tumor activity in a xenograft model. In contrast, healthy human B cells were spared. Finally, the combination of the CRISPR/Cas9 technology with CAR T cell therapy may further enhance the safety and efficacy on cancer therapy (Mollanoori et al., 2018).

In summary, CAR T-cell technology can provide substantial advantages for immunotherapy and gene therapy applications. Second generation CARs, bispecific CARs, tan-CARs and iCARs have certainly widened the repertoire as described above. Combination of CAR T with CRISPR/Cas9 technology and addition of nanoparticle delivery methods has further increased the range of applications. Taking into account current development and the potential of future progress with technologies, the CAR T-cell technology presents an opportunity to achieve superiority compared to conventional chemotherapy and radiotherapy.

CRISPR

The discovery and development of the prokaryotic adaptive immune system, the CRISPR-associated Cas9 system, into a potent gene editing tool has taken not only molecular biology but also gene therapy to an unprecedented level (Lino et al., 2018). The technology has found applications in the development of model cell lines, drug target and drug mechanism discovery, development of transgene animals and plants and even in vivo human gene therapy. Delivery of CRISPR/Cas9 presents a serious challenge for therapeutic applications of gene editing (Mukalel et al., 2019). In this context, both physical methods such as microinjection and electroporation and biological methods based on viral and non-viral vectors have been applied. In the case of viral delivery, Ad, AAV and lentivirus vectors have been used, while non-viral delivery has relied on liposomes, polyplexes and gold particles.

A classic example of gene editing for gene therapy relates to homology directed repair in hepatocytes in a hereditary tyrosinemia type 1 mouse model (Yin et al., 2016). The Cas9 mRNA was delivered by LNPs while the subgenomic RNA expression cassette and homology directed repair template were delivered by AAV. Optimization of the delivery process resulted in gene editing in 6% of hepatocytes. In another approach, the proof-of-concept for CRISPR/Cas9-based gene editing for reduction of the transthyretin serum concentration was demonstrated by co-delivery of Cas9 mRNA and modified subgenomic RNA in ionizable and helper lipids (Finn et al., 2018). A single intravenous injection resulted in 70% gene editing and more than 97% knockdown in hepatocytes in mice.

The (CRISPR/Cas) system has also been engineered for gene editing approaches to treat HIV-1/AIDS (Xiao et al., 2019). In this context, CRISPR/Cas9 has been applied for targeting cellular co-factors or the HIV-1 genome to reduce HIV-1 infection and clear provirus. For instance, the CRISPR/Cas9 system has been applied to target the NF- κ B binding cassette in the U3 in the LTR region and the TAR sequences in the R region, which resulted in efficient inhibition of HIV-1 provirus transcription and replication in Jurkat cells (Ebina et al., 2013). Moreover, CRISPR/Cas9 could eliminate integrated HIV-1 genes from the host cell genome showing potential for HIV-1/AIDS treatment. In another study, it was demonstrated that the CRISPR/Cas9 system could target conserved sites in the HIV-1 LTR U3 region, which inactivated viral gene expression and restricted HIV-1 replication (Hu et al., 2014). Moreover, it was shown that the efficacy of excision of HIV-1 sequences and disruption of non-integrated proviral HIV-1 genome could be

achieved by targeting multiple sites in the HIV-1 genome (Liao et al., 2015). Viral replication and escape could be prevented by combining two effective subgenomic RNAs, which targeted different regions of the HIV-1 genome (Lebbink et al., 2017).

Another approach in HIV therapy relates to the C-C chemokine receptor type 5 (CCR5), which has a 32 bp deletion (CCR5Δ32) in a limited number of people rendering them resistant to HIV-1 infection (Galvani and Novembre, 2005). Hematopoietic stem transplantation (HSC) with CCR Δ32 donor cells can provide HIV-1 resistance for recipients, but with few donors available and a certain risk is associated with allogeneic HSC transplantation, an alternative approach is to apply the CRISPR/Cas 9 system (Cornu et al., 2015). A CRISPR/Cas9 gene editing system was established in human CD34⁺ hematopoietic stem/progenitor cells (HSPCs), which provided efficient CCR5 ablation in mice (Xu et al., 2017). The effect remained robust in secondary transplanted repopulated hematopoietic cells and most importantly HIV-1 resistance was observed. Furthermore, CRISPR-edited CCR5-ablated HSPCs were transplanted into a patient with HIV-1 infection and ALL (Xu et al., 2019). The ALL was in full remission and donor cells carrying the ablated CCR5 persisted for at least 19 months. No gene-editing adverse events were detected.

Approved gene therapy drugs

Gendicine™ was the first approved viral vector-based gene therapy drug for the treatment of head and neck cancer (Räty et al., 2008). The oncolytic Ad virus expresses the p53 tumor suppressor gene has been administered to more than 30,000 patients showing good safety and superior efficacy compared to standard therapy, especially when combined with chemotherapy and radiotherapy (Zhang et al., 2018b). A second-generation oncolytic HSV-GM-CSF vector has been approved for melanoma treatment in the United States and Europe (Fukuhara et al., 2016; Kaufman et al., 2010). Although the AAV-based treatment of the rare monogenic inherited disease lipoprotein lipase deficiency (Glybera™) was approved in Europe (Ylä-Herttuala, 2015) the license for its clinical use was not renewed because of insufficient demand. The first gene silencing drug to be approved was the LNP siRNA drug Onpattro for the treatment of polyneuropathy caused by transthyretin amyloidosis (Garber, 2018).

Several viral vector-based vaccines have received approval. The EBOV vaccine based on the VSV-ZEBOV vector was approved in December 2019 under the brand name Ervebo (Ollmann Saphire, 2020). Moreover, several Ad vector-based COVID-19 vaccines have received Emergency Use Authorization (EUA). For instance, the ChAdOx1 nCoV-19 received an EUA in the United Kingdom in December 2020 and in January 2021 in Europe. The single administration Ad26.COV2.S vaccine has also been approved in the United States. Moreover the Russian Sputnik V rAd26-S/rAd5-S received approval in Russia and some other countries.

In the context of CART T cell technology, CD19-derived CAR T cells have been approved by the FDA for use in children and young adults for treatment of ALL and in adults for DLBCL therapy. For additional information on approval of gene therapy-based drugs a list can be found at <https://www.fda.gov/vaccines-blood-biologics/cellular-gene-therapy-products/approved-cellular-and-gene-therapy-products>.

Conclusions

After the setbacks in the 1990s with the death of a patient treated for the non-life-threatening ornithine transcarbamylase deficiency (OTC) with an Ad vector (Lehrman, 1999) and SCID-X1 patients developing leukemia after treatment with a retrovirus, gene therapy (McCormack and Rabbitts, 2004) encountered a major crisis with clinical trials putting on hold and funding drying out and pharmaceutical and biotech companies pulling out of gene therapy programs. Fortunately, gene therapy survived through intensive vector and protocol development. Substantially improved safety and delivery methods have been established placing the whole area of gene therapy in a new light. In addition to classic gene therapy applications based on non-viral and viral vector, alternative approaches using nanoparticle-based delivery, gene silencing, gene editing and CAR T cell technologies. The vaccine development has also seen unprecedented progress, partly due to the enormous resources dedicated to COVID-19 vaccine development. Both gene therapy drugs and vaccines have been approved and with hundreds of drug candidates in the pipelines and hundreds of clinical trials in progress, gene therapy finally seems to live up to the promise as the medicine of the future.

Glossary

Bacterial exopolysaccharides Bacterial polysaccharides loosely attached or completely detached from the bacterial surface.

Dietary supplement Supplement or nutraceutical taken in the form a tablet, capsule, pill, powder or liquid.

Essential nutrient A nutrient that must be obtained through the diet, as its synthesis by an organism is insufficient.

Mineral supplement Inorganic element required by organisms as an essential nutrient in the diet and manufactured as a supplement.

Nutrient Substance needed by an organism to survive as well as to perform its basic functions.

Nutritional supplement Supplement that provides one or more nutrients an individual may otherwise not consume or absorb in sufficient quantities.

Probiotic Living microorganisms that are ingested to increase microbiota populations, intending to produce health benefits in the host and manufactured as a supplement.

Supplement Product taken by an organism to substitute a dietary constituent or to increase the physiological concentrations of a biochemical or biological component.

Synthetic supplement Supplements produced in a laboratory using a standardized procedure.

Vitamin supplement Organic compound required by organisms as an essential nutrient and manufactured as a supplement.

Introduction

For many centuries, traditional medicine has used products of animal or vegetable origin to treat various ailments including immune alteration and since the mid-20th century, when dietary supplementation became widely adopted, the production and consumption of natural and synthetic supplements has been on the rise. Currently, in many countries, more than half of the adult population consumes at least one daily supplement (Carpenter, 2003; Kiely et al., 2021). Examples of supplements with the highest rates of consumption include multivitamins, omega-3 oil, iron, calcium, probiotics and echinacea (Alpert, 2017). The mechanism of action of most of these compounds, including how they regulate immune function, has only recently been elucidated. In this article we will detail the most relevant information regarding the immunomodulatory role of synthetic and natural supplements. While the consumption of supplements may be highly convenient in individuals with nutrient or immune deficiencies, healthy individuals currently consume most supplements and do so in an unwarranted fashion. Moreover, excessive supplement consumption generates physiological and economical adverse effects (Ronis et al., 2018). Therefore, it is crucial that the public and health sectors properly regulate supplement consumption.

Synthetic nutritional supplements

The consumption of a rich and varied diet remains the most sensible method for continual maintenance of adequate physiological concentrations of macro- and micronutrients, a beneficial microbiome and proper immune system functioning (Durack and Lynch, 2019). Currently, supplementation is recommended exclusively for individuals with improper diets, or with malabsorptive, metabolic or nutrient consumption processes (Ames, 2004). Malnutrition, the lack of adequate physiological concentrations of macro- and micronutrients, is the most prevalent cause of secondary immunodeficiency. Half of the world's population suffers from this condition, which generates predisposition towards infection, which can further worsen nutrient deficiency (Chinen and Shearer, 2008). Importantly, supplementation may prevent both the occurrence and progression of infections in malnourished individuals (Mme, 2010).

In healthy individuals, nutritional requirements demand an average consumption of 100–1000 mg of specific micronutrients per day and 10–300 g of macronutrients per day. In patients with malabsorption or those that require parenteral nutrition or tube feeding, higher nutrient quantities are needed (Kennel et al., 2010). Nutritional supplements include vitamins and minerals (micronutrients), as well as proteins, lipids and carbohydrates (macronutrients) (Morris and Mohiuddin, 2020). The absorption profiles of nutrients found in food are generally greater than those found in synthetic supplements. Nevertheless, synthetic supplements present the advantage of containing copious quantified amounts of one or more nutrients, facilitating their administration in individuals with nutrient deficiencies (Thiel, 2000).

Macronutrients

Macronutrients are calorie-providing nutrients that need to be consumed in significant and balanced amounts, especially by athletes, to maintain body functions. Three broad categories of macronutrients exist: proteins, carbohydrates and fats. Individuals with recurrent or chronic diseases, as well as those with an improper diet are generally unable to obtain adequate amounts of macronutrients, thus affecting various physiological functions, including their immune response. Importantly, macronutrient supplementation is recommended in patients with a body mass index below 18.5, as it leads to a significant weight improvement after 2 months (Alpert, 2017).

Proteins/amino acids

Proteins, the most abundant macromolecules in the human body, are amino acid polymers linked by peptide bonds that provide the same energy density as carbohydrates. Protein depletion weakens the immune system by diminishing white blood cell count and immune protein synthesis and may occur after prolonged starvation, recurrent or chronic infections and/or cancer (Alpert, 2017). In addition, during infection, muscle protein is catabolized to provide amino acids for immune cell, protein, and peptide synthesis (Batatinha et al., 2019). Protein-calorie malnutrition is one of the most common forms of malnutrition in underdeveloped countries and leads to HIV disease and tuberculosis (TB) progression. In TB patients, protein supplementation favors treatment completion and sputum conversion (Koethe et al., 2009). In addition, supplementation with whey protein improves nutritional status, immunity and inflammation resolution in protein deprived patients (Bumrungpert et al., 2018). Crucially, protein supplementation is not associated with adverse effects when balanced with other macronutrients (Koethe and Von Reyn, 2016).

Protein malnutrition diminishes plasma amino acid concentrations and alters: (1) proliferation and activity of macrophages and of T, B and natural killer (NK) lymphocytes (2) cellular redox state (3) antibody, cytokine and cytotoxic compound production. Supplementation with specific amino acids (particularly glutamine, arginine, and cysteine) in animals or humans with malnutrition and infection may improve immune status, morbidity and mortality (Li et al., 2007). Glutamine is the most abundant amino acid in the body and is essential for protein synthesis in all cell types. Moreover, during immune activation, immune cells initiate glutaminolysis depleting glutamine reserves (Batatinha et al., 2019). Therefore supplementation with glutamine and other highly

relevant amino acids, such as the branched-chain amino acids (leucine, isoleucine and valine), whose depletion lowers lymphocyte proliferation and increases susceptibility to infection is sensible in individuals with protein malnutrition (Calder, 2006). For an in-depth analysis of the individual immunomodulatory effects of supplementation with different amino acids, the authors refer the reader to the detailed review by Li et al. (2007).

Lipids

Fatty acids are macromolecules that take part in vital cellular processes including energy generation, protein conformation and gene expression regulation. These macromolecules modulate immunological processes including T-cell signalling, phagocytosis, eicosanoid formation and complement system activation. Fatty acids can be classified according to their structural characteristics, including carbon saturation: saturated fatty acids possess no double carbon bonds, and unsaturated fatty acids possess one or more double carbon bonds. Importantly, modifying diet composition alters physiological fatty acid concentrations and cellular functioning (Trichet, 2010).

Polyunsaturated fatty acids, including omega-3 and to a lesser extent omega-6 fatty acids, are the most sought-after fatty acid supplements, although assorted lipid supplements are currently being tested for the treatment of malnutrition (Dewey and Arimond, 2012).

Omega-3/6 fatty acids are polyunsaturated fatty acids that possess a double bond three/six atoms apart from the terminal methyl group (Gutiérrez et al., 2019). Eicosapentaenoic acid and docosahexaenoic acid found in fish and other seafood oils, and alpha-linolenic acid found in plant oils, represent the three main omega-3 fatty acids. Fish oil supplements have been shown to decrease inflammatory markers in patients with cardiovascular disease, colorectal cancer and rheumatoid arthritis (Knapp and FitzGerald, 1989; Wang et al., 2006; Silva et al., 2012). While plant oil supplementation has shown to reduce inflammation markers in hyperlipidemic individuals (Micallef and Garg, 2009). In addition, supplementation with omega-3/6 fatty acids diminishes inflammation markers in patients with skin inflammatory diseases such as psoriasis and acne (Balić et al., 2020).

Pro-resolving mediators, metabolites of omega-3 fatty acids, comprise leukotrienes, maresins, protectins, prostaglandins, resolvins and thromboxanes. These mediators downregulate proinflammatory cytokine and chemokine production, MHC and co-stimulatory molecule expression, basophil, mast cell and eosinophil activation and Th1 and Th17 differentiation (Gutiérrez et al., 2019). Omega-3 fatty acids appear to reduce inflammatory gene expression through the blockade of NF-κB and increase anti-inflammatory gene expression through stimulation of the peroxisome proliferator-activated receptor γ (PPAR- γ) (Calder, 2017). Moreover, through Treg differentiation, omega-3 fatty acid supplementation has improved autoimmune disease (Farjadian et al., 2016) as well as decreased the severity of mast cell-associated diseases including atopic dermatitis (Haitz and Anandasabapathy, 2015).

Carbohydrates

Carbohydrates are macromolecules composed of carbon, hydrogen and oxygen atoms and are essential macronutrients, especially for malnourished populations as they help in consumption compliance by adding taste and flavor (Kokkinidou et al., 2018). These macromolecules are further divided into monosaccharides, disaccharides oligosaccharides and polysaccharides based on the number of sugar groups that conform them. Monosaccharides, disaccharides and oligosaccharides are not frequently consumed as immunomodulatory supplements, except for chitoooligosaccharides and other prebiotics that possess selective immunostimulant and anti-inflammatory actions (Hyung et al., 2006). On the other hand, polysaccharides possess significant immunomodulatory effects. For an in-depth analysis of the immunomodulatory effects of polysaccharide supplements, the authors refer the reader to the detailed review by Ramberg et al. (2010).

Micronutrients

Vitamins and minerals are essential compounds required in lesser quantities than macronutrients. Micronutrient supplementation has been shown to enhance resistance to illness and improve immune responses in frequently malnourished populations such as the elderly, vegans and pregnant women (Bogden et al., 1994; Alpert, 2017). Multivitamins (synthetic supplements containing several vitamins and minerals) should preferably be used when treating multiple micronutrient deficiencies, such as in individuals belonging to the previously mentioned frequently malnourished populations, as micronutrients may compete with each other for intestinal absorption. Multivitamin supplementation may therefore not be ideal in populations lacking a single micronutrient (McCormick, 1999). Equally important, supplementation given to individuals with adequate physiological concentrations of micronutrients does not appear to affect their immune response (Mitchella et al., 2003).

Minerals

In biochemistry, essential trace elements are inorganic compounds obtained from the diet and required in very small quantities to sustain an organism's physiological requirements (Sabine, 1967). Adequate assessment of trace mineral concentrations is highly complicated and expensive, and therefore rarely evaluated (Delves, 1985). Furthermore, clinical trial data regarding mineral supplementation is inconsistent. Here we will focus on mineral supplements with well-known immunomodulatory properties.

Zinc

Zinc, the most abundant intracellular trace element, enhances skin and mucosal membrane integrity and improves innate and adaptive immunity (Alpert, 2017). Its deficiency affects 2 billion people worldwide, most of which are elderly and/or live in underdeveloped nations, hindering innate immune protection and favoring infection, oxidative stress and adaptive immune overreactivity (Wessels et al., 2017). Zinc supplementation potentiates acute and chronic viral and bacterial clearance (Acevedo-Murillo et al., 2019; Read et al., 2019) and has saved millions of children's lives in developing countries (Bajait and Thawani, 2011).

Selenium

Selenium influences the cellular innate and adaptive immune responses, as well as antioxidant function (Wintergerst et al., 2007). Adequate selenium status is essential in counteracting certain viral infections and is considered the most vital nutrient for AIDS patients (Broome et al., 2004; Alpert, 2017). Selenium's organic supplementation possesses a better absorption profile than its inorganic counterpart and in patients with autoimmune thyroiditis and Graves' disease, it reduces antithyroperoxidase antibody levels and improves life quality (Ventura et al., 2017).

Iron

Iron favors immune cell proliferation, maturation and polarization (specifically in lymphocytes) and protects against infection (Alpert, 2017). Importantly, iron deficiency is highly prevalent in developing countries and unfortunately in vivo and in vitro studies have reported adverse effects of oral iron supplementation on gut microbiota composition, affecting immune regulation (Kortman et al., 2017). Furthermore, as pathogenic microorganisms use iron as a nutrient source, a "goldilocks threshold" when administering iron supplementation to an infected individual must be reached to reap the most immune benefits without favoring the pathogen (Agoro and Mura, 2019).

Vitamins

Vitamins and their metabolites regulate critical immunological processes through their coadjuvant functions. Vitamins C and E and members of the B complex act nonspecifically, while vitamins A and D, through their metabolites, directly influence the immune response by binding to nuclear-hormone receptors (Mora et al., 2008). Crucially, vitamin deficiency is a significant suppressor of immune function that increases susceptibility to cancer and infection (Alpert, 2017).

Vitamin A

Vitamin A is obtained from the diet either as retinol, retinyl esters or β -carotene. Retinol supplementation directly regulates innate and cell-mediated immunity as well as antibody responses, while supplementation with β -carotene improves IL-2 receptor expression and NK cell proliferation (Watson et al., 1991; Santos et al., 1996). In tissues, retinol, retinyl esters and β -carotene are oxidized to all-trans-retinal, an active form of vitamin A (Moise et al., 2007) and then to retinoic acid, another active form of vitamin A (Mora et al., 2008). DCs from Peyer's patches can synthesize retinoic acid from vitamin A (Lampen et al., 2000). Retinoic acid regulates antigen presentation and DC function through retinoid X receptor stimulation (Geissmann et al., 2003). In addition, retinoic acid promotes T-cell proliferation, Th2 and cytotoxic responses through retinoic acid receptor stimulation (Mora et al., 2008). During vitamin A deficiency, mucosal epithelium integrity is compromised, favoring pathogen invasion. Moreover, during vitamin A deficiency an increase in the severity and duration of infectious diseases generally occurs (Underwood and Arthur, 1996; Tang and Smit, 1998). For an in-depth analysis of the individual immunomodulatory effects of vitamin A supplementation, the authors refer the reader to the detailed review by Villamor et al. (Villamor and Fawzi, 2005).

Vitamin B

The vitamin B complex includes eight B vitamins, however we will detail three of them with well-known immunomodulatory properties. Vitamin B6 regulates the adaptive immune response by modulating thymus size, B and T lymphocyte maturation, proliferation and function. Deficiency of this vitamin is commonly found in young malnourished women, elderly and AIDS patients (Cheng et al., 2006; Alpert, 2017). Large dose supplementation may correct deficiency of this vitamin, and may also suppress pro-inflammatory cytokine production in patients with autoimmune disease (Huang et al., 2010). Folate, also known as vitamin B9 or folacin, is required for cell division processes including DNA synthesis and cell-mediated immunity. Vitamin B9 deficiency alters the induction of intestinal T regulatory (Treg) cells favoring intestinal inflammation and can be corrected with folic acid (the man-made precursor of folate) supplementation (Mikkelsen and Apostolopoulos, 2019). Vitamin B12 regulates leukocyte division and antibody formation. Healthy older immunocompetent adults with low serum concentrations of vitamin B12 show impaired antibody responses to vaccines (Alpert, 2017). While supplementation with B12 may improve vaccine-specific responses (Siddiqua et al., 2016).

Vitamin C

Vitamin C or ascorbic acid, stimulates diverse leukocytes functions, specifically neutrophil and monocyte chemotaxis, T lymphocyte proliferation and cytokine and immunoglobulin synthesis. Under physiological conditions, vitamin C functions as an antioxidant

in plasma. However during infection, vitamin C levels diminish after their consumption by white blood cells and supplementation allows immunological function recovery (Alpert, 2017). To address the topic of vitamin C supplementation and immunomodulation the authors recommend the detailed review by Webb and Villamor (2007).

Vitamin D

Regarding immunomodulation, the most physiologically relevant form of vitamin D is probably vitamin D₃ or cholecalciferol, a dietary prohormone whose synthesis can be generated in the skin from 7-dehydrocholesterol after sunlight exposure. Vitamin D₃ can undergo transformation within the liver to the main circulating form of VD₃, 25-dihydroxyvitamin D₃ (25(OH)VD₃) or calcifediol. Finally, 25(OH)VD₃ metabolization to 1,25(OH)₂VD₃ or calcitriol (the most physiologically active VD₃ metabolite) occurs in the kidneys. Immune cells (T and probably B lymphocytes, macrophages and some dendritic cells (DCs), such as monocyte-derived DCs and dermal DCs) can also metabolize VD₃ and concentrate its specific actions within immune microenvironments, limiting undesirable systemic effects (Van Etten and Mathieu, 2005; Holick and Chen, 2008; Mora et al., 2008; Rolf et al., 2014). Interestingly, immature thymocytes and mature CD8⁺ T lymphocytes possess the highest concentration of vitamin D receptors (Alpert, 2017).

Innate immune cells may be inhibited by calcitriol. Calcitriol inhibits differentiation, maturation and immunostimulatory capacity of DCs by downregulating CD40, CD80, CD86 and MHC II expression. Furthermore, by suppressing their IL-2 synthesis, calcitriol blocks Th1 responses and increases IL-10 expression (Mora et al., 2008). However, calcitriol acts primarily in the adaptive immune response, inhibiting T-cell proliferation, IL-2 and interferon- γ (IFN γ) production, as well as cytotoxic CD8 T-cell activity (Mora et al., 2008). Moreover, calcitriol's inhibitory effects are mostly observed in effector and memory T-cells, as they express more vitamin D receptor (Veldman et al., 2000). In addition, calcitriol suppresses primary mixed-lymphocyte reactions and cytotoxic T-cell responses (Meehan et al., 1992). Overall, Calcitriol blocks Th1 cytokines by decreasing IFN γ production and favoring IL-4 production (Van Etten and Mathieu, 2005). Crucially, calcitriol inhibits Th17 responses due to its inhibition of IL-6 and IL-23 production and expansion of forkhead box protein 3 (FOXP3⁺) Treg cells. Calcitriol also decreases B-cell proliferation, plasma-cell differentiation and IgG secretion and may play a role in the pathophysiology of system lupus erythematosus (SLE) (Mora et al., 2008).

Vitamin D reference ranges in the population vary significantly depending on the geographic location, sampling season, and ethnic background of the studied population. During winter, in northern latitudes, close to three quarters of the population may have some degree of vitamin D deficiency. In other locations, 50% or more of patients commonly encountered in clinical practice may have vitamin D deficiency, especially those with darker skin color (Reusch et al., 2009). Measuring total 25(OH)D levels may be the best way to assess body stores of vitamin D. Importantly, clinicians should avoid measuring 1,25(OH)₂D levels in the diagnosis of hypovitaminosis D, for it may lead to a misinterpretation of vitamin D status due to the fact that calcitriol levels may appear in normal or even elevated range in patients with vitamin D deficiency as a result of elevated parathyroid hormone levels (Kennel et al., 2010). The consequences of vitamin D deficiency include impaired immunity and increased risk of autoimmunity (DeLuca, 2004). Furthermore, appropriate supplementation with vitamin D₃ in susceptible populations taken with a fat containing meal may significantly reduce the risk of respiratory and systemic infections, possibly by increasing the production of antimicrobial peptides such as cathelicidin (Kennel et al., 2010; Camargo et al., 2012; Gunville et al., 2013; Martineau et al., 2017).

Vitamin E

Vitamin E is an antioxidant that protects cell membrane integrity from free radicals and due to their high polyunsaturated fatty acid content, leukocyte cell membranes are particularly vulnerable (Coquette et al., 1986). Approximately, 66% of older adults have low levels of vitamin E (Alpert, 2017) and disturbingly, vitamin E supplementation is frequently taken at improper concentrations that do not provide therapeutic effects (Meydani et al., 1997). Vitamin E deficiency increases PGE₂ and plasma lipid peroxide levels and consequently decreases delayed type hypersensitivity and antibody responses, as well as IL-2 production and lymphocyte mitogenic responses to concanavalin A. Proper supplementation of this vitamin replenishes these responses (Meydani et al., 1986).

Other synthetic supplements

Non-vitamin and non-mineral synthetic supplements (informally referred to as "pseudovitamins") include biochemical compounds, such as certain antioxidants and coenzymes that are usually irretrievable in significant quantities from the diet and may improve the host's immune response. Due to the vast amount of synthetic non-nutritional supplements, in this section we will only mention two groups of these supplements which appear to have important immunomodulatory actions. For a more in depth review of synthetic supplements, including their immunomodulatory actions, the authors recommend the compendium by Seyed Mohammad Nabavi (2018).

Ketones are products derived from fatty acids that can be converted and shunted into the citric acid cycle for energy generation. Despite the fact that various natural and synthetic ketone supplements have been produced, their consumption is currently not recommended, due to their undesired proinflammatory effects including NLRP3 inflammasome activation (Correia-Melo et al., 2019; Neudorf et al., 2019).

Glutathione (GSH) is an anti-inflammatory antioxidant whose concentrations regulate lymphocyte activity. Supplementation with GSH or with its precursor *N*-acetylcysteine is associated with cytokine balance and downregulation of inflammation in the

elderly and in individuals with chronic inflammation or chronic infection. However, several studies have reported harmful, pro-oxidant effects of these supplements. For this reason, GSH, its precursor and other antioxidant supplements should be prescribed with extreme caution (Ju et al., 2017).

Plant-derived supplements

Plants and their metabolites have been typically used in traditional medicine for their immunomodulatory properties and arguably represent the largest category of supplements (Dell'agli et al., 2013). Nonetheless, it's important to mention that these supplements have induced pathological reactions in patients including severe allergies and drug interactions (Gertsch et al., 2011; Brewer and Chen, 2017; Hudson et al., 2018). Due to the vastness of plant-derived supplements, in this section we will only describe those with well-known immunomodulatory properties. If the reader wishes to consult a more in-depth review of plant-derived supplements including their immunomodulatory actions, the authors recommend the detailed reviews of Sultan et al. (2014) and Seyed Mohammad Nabavi (2018).

Camellia sinensis is a shrub belonging to the Theaceae family used for the preparation of green tea and as a supplement. The anti-inflammatory effects of its metabolites (flavonoids, catechins and polyphenols) have been observed in non-alcoholic steatohepatitis, cancer, cardiovascular disease and asthma. Additionally, these compounds possess antiviral, antibacterial, antiparasitic and immunoactivating qualities. More specifically, they are capable of decreasing Th17 and neutrophil, as well as IgE and histamine responses while stimulating NK cell cytotoxicity (Aboulwafa et al., 2019; Chen et al., 2019).

Dzherelo is a concentrated aqueous alcohol extract composed of various plant-derived products that has been used extensively in the treatment of autoimmune disease, malignancy, as well as chronic bacterial and viral infections. Clinical studies indicate that its consumption increases CD4 T-lymphocytes and decreases HIV viral and TB bacterial load, synergizing with drug therapies and alleviating hepatotoxicity. In addition, Dzherelo appears to reduce HIV/AIDS-opportunistic infections and reverse TB-associated wasting (Zaitzeva et al., 2009).

Fruit-derived supplements

Resveratrol is a widely known polyphenolic stilbenoid found in grapes, blackberries, peanuts, rhubarb, and several other plants. It has been used for the prevention and progression of chronic inflammatory diseases, such as diabetes, obesity, cardiovascular and neurodegenerative diseases, among other conditions. Resveratrol regulates leukocyte activity, as well as the synthesis of proinflammatory cytokines through nuclear factor- κ B (NF- κ B) and toll-like receptor (TLR) regulation. In addition, resveratrol inhibits the expression of proinflammatory eicosanoids (Harikumar and Aggarwal, 2008; Pennisi et al., 2017; Malaguarnera, 2019).

Mangosteen (*Garcinia mangostana*) is a fruit of Asian origin, belonging to the Guttiferous family. It contains a wide variety of biologically active molecules, including catechins, polyphenolic compounds (such as flavonoids, tannins and anthocyanins), vitamins B1, B2, B6 and C; minerals (potassium, phosphorus, calcium and iron) and xanthenes that have anti-inflammatory and antioxidant properties (García Font and Ortega Hernández-Agero, 2011). Mangosteen derivatives with specific immunomodulatory properties include the xanthenes α -mangosteen and γ -mangosteen (Chairungsri et al., 1996). In a murine model of asthma it was reported that these xanthenes reduced disease symptoms (Jang et al., 2012). Likewise, in vitro and in vivo studies showed that *Garcinia mangostana* extracts possess anti-inflammatory effects through the regulation of prostaglandins, CRP and NF- κ B (Nakatani et al., 2002, 2004; Tang et al., 2009). In humans, these extracts increased peripheral complement system components and T lymphocyte proliferation (Tang et al., 2009).

Root-derived supplements

Echinacea spp., a plant native to eastern and central North America and used by indigenous tribes, has been used to treat upper respiratory tract infections due to its selective pro- and anti-inflammatory properties (Schoop et al., 2006). *Echinacea*'s Th1 cytokine inhibition appears to be induced through stimulation of the endocannabinoid system (Chicca et al., 2009).

Ginseng, obtained from the root of *Panax quinquefolius*, is a herb that has been widely used in traditional medicine to induce immune homeostasis and prevent infection. Ginseng contains several pharmacological components, such as tetracyclic triterpenoid saponins (ginsenosides), polyacetylenes, polyphenolic compounds and acidic polysaccharides (Kang and Min, 2012; Riaz et al., 2019). Ginseng extracts have been reported to activate macrophages and have the ability to modulate DC function, increase cytokine production and enhance T lymphocyte activation (Shin et al., 2002; Riaz et al., 2019). In addition, these extracts are capable of promoting Th1 cell differentiation and CD8⁺ T lymphocyte and NK cell cytotoxicity during intracellular infection (Riaz et al., 2019). Ginseng has also been reported to promote humoral immunity through the potentiation of antibody production (Liou et al., 2005). On the other hand, ginseng improves chronic inflammatory disease symptoms, through pro-inflammatory cytokine reduction (Kang and Min, 2012; Riaz et al., 2019).

Ginger (*Zingiber officinale*) is a Chinese flowering plant that belongs to the Zingiberaceae family. The rhizome (the part of the stem that grows under the ground) is generally used for production of the supplement and contains terpenes, phenolic compounds (gingerol, shogaol and paradol) and some flavonoids (quercetin, capsaicin). Ginger supplementation been used as an adjuvant treatment in rheumatic, gastrointestinal and cardiovascular diseases due to its anti-inflammatory effects (Mashhadi et al., 2013;

Mahassni and Bukhari, 2019). Its anti-inflammatory actions include the reduction of CRP and TNF- α serum levels in animal models and humans (Tripathi et al., 2006; Morvaridzadeh et al., 2020). It has been proposed that this effect is due to the action of 6-gingerol, which appears to inhibit the NF- κ B activation (Tripathi et al., 2006).

Curcumin is an extract from the root of turmeric (*Curcuma longa*), a plant native to India that contains different percentages of volatile and non-volatile oils, proteins, fats, minerals, carbohydrates and curcuminoids. Curcuminoids are a group of molecules made up of curcumin (60–70%), demethoxycurcumin (20–27%) and bisdemethoxycurcumin (10–15%) (Gautam et al., 2007; Abdollahi et al., 2018). Curcumin has been reported to have anti-inflammatory effects and has been used as an adjunct in the treatment of arthritis, allergies, asthma, and cardiovascular diseases. Its anti-inflammatory effects appear to be related to the modulation of T and B lymphocyte, NK cell, macrophage and DC activation, as well as a reduction in proinflammatory cytokines through the inhibition of NF- κ B and MAPK (Jagetia and Aggarwal, 2007). Furthermore, in vitro experimentation has demonstrated that curcumin inhibits STAT3 activation (Bill et al., 2012).

Garlic is a bulb derived from the flowering plant *Allium sativum*, whose supplementation has been used by Egyptian and Chinese traditional medicine. Supplementation with aged garlic extract (AGE) which contains derivatives such as sulfur-containing compounds, upregulates $\gamma\delta$ -T and NK cell proliferation and activation and appears to reduce cold and flu severity and duration (Percival, 2016). In addition, AGE supplementation decreased serum TNF- α and IL-6 blood concentrations in adults with obesity (Xu et al., 2018).

Microalgae-derived supplements

Microalgae are unicellular, microscopic algae which possess bioactive compounds, such as vitamins, lipids, carbohydrates, and pigments. Various studies have shown that microalgae have anticancer, antimicrobial, antiepileptic, anti-inflammatory activities (Riccio and Lauritano, 2019). In vitro experimentation has demonstrated that microalgae block the release of TNF- α and nitric oxide (Samarakoon et al., 2013; Lauritano et al., 2016). While in animal models, microalgae have been shown to have protective effects in inflammatory bowel disease (Lavy et al., 2003). Finally, in patients with non-alcoholic fatty liver, the administration of *Chlorella vulgaris* decreased TNF- α concentrations (Ebrahimi-Mameghani et al., 2017).

In addition, different compounds derived from microalgae, such as sulfo-polysaccharides, sulfated lipids, polyunsaturated fatty acids and astaxanthin possess immunostimulant activities (Lauritano et al., 2016). Extracts from multiple microalgae appear to be capable of inducing IL-6 production in human peripheral blood mononuclear cells (Cutignano et al., 2015). Furthermore, in a murine model, the administration of *Chlorella stigmatophora*, a marine microalgae, increased phagocytic activity in macrophages. While supplementation with *Euglena gracilis*, a unicellular microalgae, increased the activity of NK cells and TNF- α and IL-6 levels (Riccio and Lauritano, 2019). Unfortunately, the precise immunostimulatory mechanisms of microalgae have not yet been elucidated (Riccio and Lauritano, 2019).

Perhaps the most popular microalgae supplement is spirulina, a microalgae with a phycocyanin (blue) and chlorophyll (green) structure. Spirulina is rich in several macro- and micronutrients and possesses antioxidant and more than 50 reported immunomodulatory properties, including upregulation of IgA, Th1 and cellular immunity, as well as downregulation of histamine, Th2 cytokine and IgE blood concentrations. Unfortunately, there have been reports of patients that developed autoimmune disorder exacerbations after taking spirulina as well as other microalgae-derived supplements (Lee and Werth, 2004).

Prebiotics

The microbiota, the collection of microorganisms within the human body, plays a fundamental role in generating immunological tolerance and integrity throughout the digestive tract (Galdeano and Perdigón, 2004). Among the metabolites produced by the microbiota, are short-chain fatty acids (SCFA), which possess anti-inflammatory properties such as the induction of regulatory cells and cytokines (Morrison and Preston, 2016). However, when dysbiosis (altered microbiota populations) is present, SCFA production decreases and long chain fatty acid production increases, promoting proinflammatory immune cell activation and intestinal permeability (Machate et al., 2020). Crucially, inflammation caused by dysbiosis, has been associated with inflammatory bowel disease, insulin resistance and obesity (Silva Figueiredo et al., 2017; Zhang et al., 2017; Machate et al., 2020).

Prebiotics are insect and plant-based compounds that favor microbiota growth. Most of these compounds are rich in fiber, and are thus nutritious for the large intestine's commensal microbiota and improve its constitution (Davani-Davari et al., 2019). Crucially, if commensal microbiota species are absent in the host due to previous disease or drug therapy, the beneficial effects of prebiotics are unlikely to be observed (Macfarlane et al., 2008). The most used prebiotics are fructooligosaccharides, inulin, isomaltooligosaccharides, lactulose, lactosucrose and galactooligosaccharides. These are obtained in foods such as whole grains, bananas and green leafy vegetables, but can also be found in the form of supplements (Azad et al., 2018; Davani-Davari et al., 2019). In vitro, as well as human and animal model experimentation, has demonstrated that prebiotics can generate immunomodulatory effects in the intestinal mucosa and lymph nodes, as well as in distal organs such as the spleen. These effects include enhanced synthesis and secretion of cytokines and immunoglobulins, as well as improved vaccine and inflammation resolving responses (Macfarlane et al., 2008; Zhang et al., 2017).

Prokaryotic-derived supplements

Probiotics

Probiotics are live microorganisms, which are consumed to improve microbiota composition. The most used genus of probiotics include *Lactobacillus*, *Bifidobacterium*, *Enterococcus*, *Lactococcus*, *Streptococcus*, *Saccharomyces*, among others (Azad et al., 2018). Most probiotics are bacteria which produce lactic acid and can be consumed in the diet (yogurt, fermented milks or products), and they can also be found in large numbers as commercial supplements (Wilkins et al., 2017; Azad et al., 2018). Probiotics act by fermenting indigestible foods and their functions can be classified as metabolic, protective and trophic (Girardin and Seidman, 2011). Through the production of non-toxic metabolites and other actions, probiotics compete for the exclusion of local pathogens, nurture, mature and differentiate resident and distant immune cells, as well as strengthen the intestinal barrier (Kau et al., 2011; Bermudez-Brito et al., 2012; Adak and Khan, 2019).

In recent years, it has been reported that probiotics are capable of modulating humoral and cellular immunity, in addition to functioning as an immune barrier by preventing the growth of pathobiont and pathogenic microorganisms (Kau et al., 2011; Bermudez-Brito et al., 2012). In vivo effects of probiotics include increased IgA production and decreased pro-inflammatory cytokine production (Azad et al., 2018). For example, it was reported that the administration of *Bifidobacterium bifidum* R0071, *Bifidobacterium infantis* R0033, and *Lactobacillus helveticus* R0052 in children increased the concentration of IgA in saliva and the digestive tract (Xiao et al., 2017). In addition, in a murine model, *L. casei* DN 11400, found in breast milk, improved mucosal immunity by increasing the amount of T and B lymphocytes and secreted IgA (Galdeano et al., 2009; Azad et al., 2018).

Probiotics in several studies have shown the ability to regulate inflammation not only in the gastrointestinal tract but also in distal organs. Recently, “sterilized probiotics” or paraprobiotics have also demonstrated immunomodulatory potency beyond their viability (Kanauchi et al., 2018). The immunomodulatory effects of probiotics have become relevant for the treatment of chronic degenerative diseases, which usually present with deregulation of the gut microbiota. Recent studies have associated dysbiosis with the pathogenesis of psychiatric disorders such as depression and schizophrenia (Fond et al., 2020). Inflammation due to dysbiosis has been described to cause tryptophan metabolism alterations concomitant with a decreased synthesis of serotonin and an increased synthesis of kynurenine. The accumulation of this last compound, which is capable of crossing the blood-brain barrier, may cause significant central nervous system adverse effects (Waclawiková and El Aidy, 2018). Importantly, probiotic consumption has been associated with a reversal of this pathological process and symptom improvement in several neuropsychiatric diseases including schizophrenia. Experimental studies nevertheless remain inconclusive regarding the role of probiotics in depression (Grover et al., 2019).

Other prokaryotic derived supplements

Bacterial and other microbial derived macromolecules such as exopolysaccharides, enzymes and metabolites (also termed “postbiotics”) represent a promising tool in the field of immunomodulatory supplements and clinical studies evaluating these compounds are currently underway (Descamps et al., 2019; Angelin and Kavitha, 2020).

Mammal-derived supplements

Mammal-derived supplements include immune and hormonal products discovered in mammals which can be obtained naturally or synthetically.

Dialyzable leukocyte extracts (DLE)

DLE are molecules weighing less than 12 kDa that are obtained from the breakdown of leukocytes and their subsequent dialysis. This process was described by Dr. Sherwood Lawrence in the 1940s when he controversially proposed that components of these dialysates transfer the ability to generate a specific immune response. Generally, the components of DLE are classified into two groups (Macías and Guaní-Guerra, 2020):

- (a) The antigen-specific or antigen-dependent fraction comprising molecules of peptide nature with a molecular weight of 3.5–6 kDa, termed transfer factor (TF).
- (b) The nonspecific antigen or antigen-independent fraction, comprises molecules below 3.5 and above 6 kDa, including the immunoregulatory molecules known as IMREG-1 and IMREG-2. Both IMREG molecules may modulate, but not transfer late hypersensitivity responses (Gottlieb and Gottlieb, 1990). Several other immunomodulatory components have been isolated from DLE. These include immunologically active peptide sequences such as the S100A9 peptide, as well as TCR portions from cytotoxic lymphocytes, among many others (Myles et al., 2017). Interestingly, some components appear to be immunostimulatory while others immunosuppressive (Sherwood Lawrence and Borkowsky, 1996).

So far, DLE (including TF) have been obtained from three sources:

1. Blood and lymphoid tissue: after the rupture of the leukocytic bundle ("buffy coat"), taken from a unit of human or animal blood, or from lymphoid tissue such as the spleen (Estrada-Parra et al., 1998; Macías and Guaní-Guerra, 2020).
2. Hen egg yolk: after hens have been exposed to specific pathogens (Xu et al., 2006).
3. Colostrum: The first form of milk, after newborn delivery from various mammals, has been used as a popular supplement in different commercial presentations. Colostrum contains macro- and micronutrients, as well as bioactive molecules such as growth factors and a plethora of antimicrobial compounds (DLE, immunoglobulins, lactoperoxidase, lysozyme, and lactoferrin). Bovine colostrum consumption has shown potentiation of different immune functions, including salivary IgA production (Mero et al., 2002). DLE have also been obtained from human and animal colostrum, which represents a relatively cheap and simple method of production. And importantly, preliminary studies suggest that DLE from different animal sources possess similar immunomodulatory efficacies (Altamirano et al., 2006).

Various reports using in vitro and murine models of autoimmunity have described the innate and adaptive immunomodulatory effects of DLE and TF. However, the precise immunomodulatory mechanism of action of these compounds in humans remains unclear, making their use controversial. An important effect caused by DLE and TF appears to be the induction of migration inhibitory factor (MIF), which activates macrophages and T lymphocytes and favors wound repair (Wilson et al., 1982). In addition, DLE have been used as an adjuvant treatment with mild to moderate success in several clinical studies involving patients with primary immunodeficiencies such as Wiskott-Aldrich syndrome and Ataxia-Telangiectasia; infections such as mucocutaneous candidiasis, cytomegalovirus, herpes zoster, tuberculosis, leprosy or cutaneous leishmaniasis; and autoimmune diseases such as Behcet's syndrome or chronic discoid lupus erythematosus (Gottlieb and Gottlieb, 1990; Fudenberg and Pizza, 1994; Estrada-Parra et al., 1998).

The composition of a patented DLE termed Transferon[®], which increases physiological concentrations of IFN- γ , TNF- α , and IL-6 in immunosuppressed patients, has recently been reported. This sequence includes large amounts of ubiquitin (Ub) and a variant of Ub that lacks the biterminal glycine. In a murine model of herpes zoster infection, oral administration of recombinant Ub decreased overall mortality. Furthermore, this effect was enhanced after combining Transferon[®] with Ub, suggesting that the biological properties may be partially associated this molecule. Additionally, it was postulated that Ub appears to activate the stomach's CXCR4 receptor inducing vagus nerve stimulation and an accompanying anti-inflammatory response (Vallejo-Castillo et al., 2020).

Importantly, caution should be exercised when recommending the use of DLE and TF, as they have been tested mainly as adjuvant therapy and results from one DLE cannot be extrapolated to another, because it is unknown if their component concentrations are equivalent. Therefore, it is important to emphasize that currently, there is insufficient evidence to recommend TF or DLE as supplements, and even less so as therapeutic drugs, although this may change in the future (Macías and Guaní-Guerra, 2020).

Hormones

Most synthetic hormones, such as estrogens, are not classified as supplements by governmental agencies. Instead, most of these commercial compounds are classified as therapeutic drugs due to the fact that high grade clinical evidence has demonstrated their beneficial effect in the treatment and prevention of diseases. Nonetheless, we will describe two hormones currently categorized as supplements that possess important immunomodulatory properties: melatonin and dehydroepiandrosterone (DHEA).

Melatonin is a hormone found in humans, animals, plants, fungi and bacteria in concentrations that vary according to the day/night cycle. Melatonin is synthesized from the essential amino acid tryptophan. It is produced mainly in the pineal gland and is involved in a wide variety of cellular, neuroendocrine and neurophysiological processes, such as the regulation of sleep/wake cycles (Altamirano et al., 2006). Although melatonin binds to membrane (MT1 and MT2, G coupled protein receptors) and nuclear receptors, many of its actions are receptor-independent (e.g., free radical scavenging and interaction with cytosolic proteins such as calmodulin).

Melatonin has many immunoregulatory properties. Crucially, in animals, the absence of this hormone inhibits immune maturation and activation. In contrast, a nocturnal increase of melatonin blood concentrations has been correlated with increased production of thymic hormones that aid in immune maturation (Altamirano et al., 2006). Various studies support the immunoregulatory action of melatonin on innate immunity, showing that it stimulates the production of granulocyte and macrophage progenitor cells and has a general stimulatory action on hematopoiesis. In addition, melatonin administration increases NK cell and monocyte counts and enhances the phagocytic activity of macrophages. Melatonin also appears to regulate cytokine production.

Several cell culture and animal models of infection and autoimmunity, as well as clinical studies of vaccine administration and immunosenescence therapy, have corroborated the efficacy of melatonin as an adjuvant (Srinivasan et al., 2005; Carrillo-Vico et al., 2013). The effects of melatonin in humans have been observed in neonates and adults with sepsis, demonstrating an overall improvement in clinical and laboratory parameters (Gitto et al., 2001; Biancatelli et al., 2020). Indeed, melatonin seems to have potential as an immunomodulatory supplement. In clinical trials it has been used as a coadjuvant therapy during infectious diseases (including COVID-19) and has also improved immune responses after vaccination (Biancatelli et al., 2020). However, more evidence is needed before it can be used in clinical settings.

The hypothalamus-pituitary-adrenal axis, along with other components of the endocrine system, represents a crucial regulator of immune function. An imbalance between opposing adrenal hormones, cortisol and DHEA takes place in aging and malnourished individuals which results in thymus atrophy, as well as a reduction in naïve T cell numbers and neutrophil, B and NK cell functions (Buford and Willoughby, 2008). Supplementation with DHEA or its synthetic analog 16 alpha-bromoepiandrosterone (HE2000), can restore circulating innate and adaptive immune cell populations, proinflammatory Th cytokine balance and reduce pathogenic load in individuals with different chronic infections, including TB and HIV (Reading et al., 2006; Stickney et al., 2007; Ramos-Espinosa et al., 2018). In postmenopausal women, DHEA supplementation decreased blood levels of IL-6, T CD4⁺ and CD8⁺ as well as NK cells and increased natural killer cell cytotoxicity (Casson et al., 1993). On the other hand, when used in healthy middle-aged male adults, chronic DHEA, androstenedione and herbal extract consumption increased androgen levels but not immune activity (Kohut et al., 2003).

Conclusion

If used conscientiously, supplements represent important tools in the clinical armamentarium that can potentiate several physiological functions, including the immune response. Nutrient deficiencies in patients with severe infections or with clinical manifestations of immune deficiency should be detected and treated accordingly through proper testing (Berger and Shenkin, 2006). Cheap and rapid testing for nutrient deficiency is therefore urgently needed, as current testing methods are not cost-effective for most patients (Kennel et al., 2010). Equally important is the demand for large and well-conducted clinical trials to determine supplement efficacy in diverse clinical settings and for governmental agencies to strengthen supplement regulation. Current unnecessary consumption of supplements generates excessive spending (Guallar et al., 2013) and important adverse effects in the general public including: acute intoxication, insomnia, gastrointestinal symptoms, calculi formation, hematological abnormalities, susceptibility to infection and pro-carcinogenic effects (Rutkowski and Grzegorzczak, 2012).

Introduction

Anti-inflammatory treatment of infections is challenging due to the heterogeneity of etiologic agents and complex immune interactions. Inflammation plays a central role in the pathophysiology of infections, being one of the principal body defensive mechanisms. Unfortunately, it also causes accompanying unpleasant symptoms. Typical manifestations of acute inflammation are pain (*dolor*), heat (*calor*), redness (*rubor*), swelling (*tumor*), and loss of function (*functio laesa*) (Signore, 2013). For this reason, anti-inflammatory medications of different classes have a long history of use in infections as supportive treatment to relieve accompanying symptoms. In addition, anti-inflammatory agents act as host response modifiers and might play a crucial role in managing acute and chronic infection with excessive inflammation preventing organ injury, e.g., COVID-19 (Rockwell and Ehrlich, 1990; Konstan et al., 1995). This article introduces the main groups of anti-inflammatory drugs, their use in treating infections, and associated risks. We also present a subsection on anti-inflammatory treatment in COVID-19.

Anti-inflammatory drugs in the treatment of infections

Non-steroidal anti-inflammatory drugs (NSAIDs)

Non-steroidal anti-inflammatory drugs (NSAIDs) reduce pain, lower fever, and decrease inflammation. Already Sumerians, ancient Egyptians, and Hippocrates reported the use of willow bark (the active ingredient in willow bark is salicin) as a remedy for fever, pain, and inflammation. One of the first systematic studies on anti-inflammatory drugs for infections was Edward Stone's study in 1763. He investigated the effectiveness of willow bark salicylates in treating malaria-related fever (Pearce, 2014; Norn et al., 2009).

The most popular drugs belonging to this group are ibuprofen, diclofenac, naproxen, and acetylsalicylic acid. In the United States, NSAIDs are one of the most popular drugs and account for 30 billion over-the-counter (OTC) medications sold (Green, 2001). These drugs inhibit the activity of cyclooxygenase enzymes (COX-1 and COX-2) responsible for synthesizing prostanoids from arachidonic acid. Prostanoids include prostaglandins, prostacyclins (PGE2, PGD2, PGF2, PGI2), and thromboxane (Tx). These lipid mediators exert many biological effects in the hematologic, pulmonary, renal, and cardiovascular systems. PGE2 and PGI2 are the primary pro-inflammatory prostanoids, which induce fever and increase vascular permeability, causing edema and leukocyte infiltration. PGD2 is produced by mast cells and causes an inflammatory reaction in allergic responses. Thromboxane has a central role in blood clot formation (Ehrenpreis and Kruchko, 2020).

By inhibiting COX enzymes, NSAIDs effectively reduce inflammation, fever, and pain. Thus, reducing infected patient's symptoms and signs of inflammation may provide a false sense of security and delay diagnosis of life-threatening infection (Stevens, 1995). In the early phase of the COVID-19 pandemic, public opinion started the concerns that ibuprofen may increase SARS-CoV-2 infection symptoms. The theoretical mechanism behind the severity of the disease suggested the upregulation of angiotensin-converting enzyme 2 (ACE2) receptors in human tissues. The SARS-CoV-2 virus uses these receptors to enter into human cells. In addition, some researchers also suggested that anti-inflammatory drugs may delay diagnosis leading to poor outcomes (Kragholm et al., 2021). However, a prospective cohort study conducted in the United Kingdom by Drake et al. (Drake et al., 2021) on 78,674 patients proved that NSAIDs use was not associated with in-hospital mortality, critical care admission, invasive ventilation, a requirement for oxygen, or acute kidney injury. Furthermore, a subanalysis did not indicate an increase in mortality in ibuprofen users compared to other NSAIDs-users and those not taking NSAIDs.

While using NSAIDs to treat infections, we must remember that they reduce the formation of prostaglandins and affect other components of the immune system. For example, NSAIDs inhibit granulocytes functions (aggregation, degranulation, chemotaxis, and phagocytosis). Besides, NSAIDs also enhance cytokines production, including tumor necrosis factor (TNF). Thus, even a minor

infection, usually well-controlled by an immune system, may develop life-threatening infectious processes (sudden onset of shock, organ failure, or aggressive infection) (Stevens, 1995; Kaplan et al., 1984; Giagoudakis and Markantonis, 2005; Oates et al., 1991). Furthermore, studies on mice have shown that using ibuprofen during streptococcal soft tissue infection worsens its course. Ibuprofen-treated mice had a higher mortality rate and significantly higher levels of tumor necrosis factor- α and interleukin 6. Based on the study results, the authors concluded that the use of ibuprofen in streptococcal soft tissue infections might cause severe necrotizing infections (Weng et al., 2011).

There is a piece of evidence that the use of NSAIDs in children may cause a worse course of some infectious diseases. For example, the use of ibuprofen in the management of varicella should be discouraged because current evidence shows an increased risk of subsequent skin and soft-tissue infections, mainly caused by group A streptococcal (GAS) (Mikaeloff et al., 2008; Lesko et al., 2001). There is also evidence indicating a strong association between the use of NSAIDs and severe necrotizing soft tissue infections in patients with chickenpox (Souyri et al., 2008). In addition, the pre-hospital use of ibuprofen in children may increase the risk of complicated pneumonia in children, including empyema (François et al., 2010; Le Bourgeois et al., 2016). Evidence shows the cumulative effect of ibuprofen dosing on a more significant risk of pneumonia complications in children with community-acquired pneumonia (CAP) (Krenke et al., 2018). In this research, preadmission cumulative dose of ibuprofen exceeding 78.3 mg/kg was a factor of 2.5 higher odds ratio for pneumonia complications. For these reasons, ibuprofen is not recommended to administer in children with suspicion of lower respiratory tract infection (Quaglietta et al., 2021). Some case reports also suggest a connection between the use of NSAIDs and the progression of streptococcal infections to shock and multi-organ failure (Stevens, 1995). Undertaken in the United Kingdom, population-based surveillance showed that taking NSAIDs was independently associated with increased risk for streptococcal toxic shock syndrome in patients with severe *Streptococcus pyogenes* infection (Lamagni et al., 2008). Therefore, symptomatic treatment with NSAIDs should be used cautiously during infections because a range of scientific arguments shows an increased risk of severe bacterial complications. For this reason, parallel antibiotic therapy should always be considered (Stevens, 1995; Le Bourgeois et al., 2016; Micallef et al., 2020). For recommended dosages of anti-inflammatory medications in various infections see Table 1.

Table 1 Dosage of main anti-inflammatory drugs used in infectious diseases (Tunkel et al., 2004; de Almeida et al., 2014; The Recovery Collaborative Group, 2021; Jenson, 2000; Marx and Chan, 2011).

Disease	Anti-inflammatory medication	Dosage
Infectious mononucleosis	Dexamethasone Methylprednisolone Oral prednisone	0.25 mg/kg every 6 h i.v. for 1–3 days 1 mg/kg every 6 h i.v. for 1–3 days 40 mg p.o. daily for 1–3 days
Bell's palsy	Prednisone	60 mg per day followed by the five-day taper, with a reduction of a previous day's dose by 10 mg per day
Bacterial meningitis	Dexamethasone	0.15 mg/kg i.v. every 6 h for 2–4 days
Tuberculous meningitis	Dexamethasone	12 mg/day (adults), 8 mg/day (children < 25 kg) i.m. for 3 weeks, followed by gradual taper for next 3 weeks OR 1 week of each (0.4 mg/kg/day, 0.3 mg/kg/day, 0.2 mg/kg/day, and 0.1 mg/kg/day), followed by 4 weeks of tapering oral dexamethasone therapy
COVID-19 in adults	Dexamethasone If not available: Prednisone Methylprednisolone Hydrocortisone	6 mg daily 40 mg daily 36 mg daily 160 mg daily
Inflammatory diseases in children	Ibuprofen (Children 1 year old or older) Naproxen (Children 2 years or older)	30–50 mg/day in 4 divided doses Doses greater than 40 mg/kg/day may increase the risk of adverse effects; doses >50 mg/kg/day are not recommended 10 mg/kg p.o. in 2 divided doses

Ibuprofen dosage: <https://www.drugs.com/dosage/ibuprofen.html>;

Naproxen dosage: https://www.drugs.com/dosage/naproxen.html#Usual_Pediatric_Dose_for_Juvenile_Rheum.atoid_Arthritis.

Glucocorticoids

Glucocorticoids are a group of drugs that reduces the activity of the immune system. Inside the cell, glucocorticoids attach to the appropriate cytoplasmic receptor (GR) and then pass the nuclear membrane as the glucocorticoid-GR complex. Inside the nucleus, the glucocorticoid-GR complex releases a specific molecule that binds to DNA. There are few steroid-responsive genes with glucocorticoid-responsive elements (GRE). The binding of the GR molecule to GRE may result in activation or repression of the gene (positive or negative GRE). The effects involve increasing the expression of anti-inflammatory proteins or decreasing pro-inflammatory proteins production (Rhen and Cidlowski, 2005). Some steroid-responsive genes do not express GRE itself, so the regulation is indirect via nuclear factor (NF)- κ B, activating protein (AP)-1 or cAMP-responsive element-binding protein (CREB). The third mechanism of glucocorticoids' impact on the regulation of inflammatory protein synthesis is by boosting the transcription of particular ribonucleases, which degrade mRNA, decreasing its stability and shortening half-time of some pro-inflammatory cytokines (van der Velden, 1998).

In medicine, glucocorticoids are often used in the treatment of autoimmune diseases, allergies, and asthma. They are also used to reduce symptoms and sequelae of severe infections. For example, in bacterial meningitis, glucocorticoids may reduce associated cerebral edema, increased intracranial pressure, altered cerebral blood flow, cerebral vasculitis, and neuronal injury by decreasing inflammatory response, but do not reverse the damage that occurred before treatment (Tunkel et al., 2004).

According to Cochrane Library, corticosteroids should be used in acute bacterial meningitis in children. Although they do not reduce the death rate, patients have significantly lower rates of hearing loss and other neurological sequelae. In children, the best effect was primarily observed in meningitis due to Gram-negative bacteria *Haemophilus influenzae* type b. However, these positive effects occurred only in high-income countries, and there were no significant beneficial effects in low-income countries. This phenomenon can be explained by the difference in patients' profiles on the example of African studies: usually, patients were admitted later, had many chronic conditions worsening the prognosis (malnutrition, HIV infection) or the antibiotics used in initial treatment (Brouwer et al., 2015). Nevertheless, glucocorticoids are routine adjunctive therapies to reduce the risk for neurologic sequelae. The recommended treatment according to IDSA is dexamethasone in a dose of 0.15 mg/kg IV every 6 h for 2–4 days (the first dose should be given 10–20 min before or with the first antibiotic dose) (IDSA Grade A-I). National Institute for Health and Care Excellence (NICE) recommends dexamethasone in infants and children beyond 3 months old with suspected or confirmed bacterial meningitis if lumbar puncture reveals any of the following:

1. frankly purulent cerebrospinal fluid,
2. elevated white blood cell count in cerebrospinal fluid with protein concentration above 1.0 g/L,
3. cerebrospinal fluid with white blood cell count above 1000/mcL or
4. bacteria on Gram stain.

Dexamethasone should be given within 4 h of starting antibiotics and should not be started if >12 h (NICE, n.d.).

Glucocorticoids are also mandatory adjunct therapy to antituberculous drugs in tuberculous meningitis, a severe neuroinfection causing death or severe neurologic deficits in more than half of those affected despite antituberculosis chemotherapy. A study performed in Vietnam provided clinical evidence that early treatment with dexamethasone and antituberculosis drugs improves survival among patients over 14 years of age with tuberculous meningitis, regardless of disease severity. However, dexamethasone probably does not prevent severe disability in the survivors (Thwaites et al., 2004). A Cochrane review of nine trials that included 1337 participants concluded that glucocorticoids reduce deaths by almost 25% in the short term, although they may have little or no effect on neurologic sequelae, the outcome that is less common than death. In addition, there was no difference between groups in adverse events, including gastrointestinal bleeding, invasive bacterial infections, hyperglycemia, and liver dysfunction. Thus, the possible harm is unlikely to be quantitatively important compared to the reduction in mortality (Prasad et al., 2016).

Cochrane Library also conducted a meta-analysis which suggests that the use of glucocorticoids in patients with sepsis results in a reduction in hospital or Intensive Care Unit (ICU) length of stay and probably reduces hospital mortality and mortality in 28-day and 90-day. The evidence for this statement is moderate-certain. Side effects of this therapy include increased risk of muscle weakness, hyponatremia (high-certainty evidence), and the potential risk of hyperglycemia (moderate-certainty evidence) (Annane et al., 2019). On the other hand, Surviving Sepsis Campaign does not support using corticosteroids intravenously to treat septic shock if it can be achieved by using adequate fluid therapy and vasopressors. In other cases, it is recommended to use hydrocortisone (Rhodes et al., 2017). In children, the guidelines do not indicate that using steroids is beneficial nor harmful—either hydrocortisone or no hydrocortisone may be used in case of lack of hemodynamic stability after adequate hydration and vasopressors were used (Weiss et al., 2020). Both in children and adults, the recommendations are classified as weak, with low quality of evidence.

Some studies also indicate the usefulness of glucocorticoids in reducing symptoms of viral infections. For example, steroid therapy may reduce the sore throat symptoms in infectious mononucleosis due to Epstein-Barr virus (EBV) infection (Rezk et al., 2015). However, the evidence to support this approach is low, and corticosteroids are not routinely recommended (Dunmire et al., 2018; Lennon et al., 2015; Luzuriaga and Sullivan, 2010). Since corticosteroids are not shown to provide substantial or sustained relief of symptoms associated with mononucleosis, they may be used based on clinical experience if concern for severe complications such as airway obstruction due to tonsils enlargement, hemolytic anemia, thrombocytopenia, mononucleosis-like aplastic anemia, or liver failure. No data is confirming the benefits of using steroids in these complications. There is no standard dosing, but

the common approach in adults is prednisone 40–60 mg/day orally for 1–3 days followed by taper over the next 7–14 days (Cohen, 2003). Reported adverse events include peritonsillar cellulitis, acute-onset diabetes mellitus, and neurologic sequelae.

Bell palsy is a subacute weakness of the facial nerve (the seventh cranial nerve), which may be idiopathic or secondary to herpes infections. In Bell's palsy complicating Herpes simplex virus (HSV) infection, steroids may shorten recovery time and increase recovery rates when added to antiviral treatment, but the difference does not seem statistically significant compared to antiviral treatment alone (Numthavaj et al., 2011). In idiopathic Bell palsy, corticosteroids are recommended by the American Academy of Neurology since they increase the likelihood of complete facial motor function recovery (Gronseth and Paduga, 2012) (Strong recommendation). Bell Palsy Working Group, Canadian Society of Otolaryngology—Head and Neck Surgery and Canadian Neurological Sciences Federation recommend using corticosteroids for all patients with Bell palsy (de Almeida et al., 2014). Various dosing regimens have been used, including prednisolone 25 mg twice daily for 10 days, prednisolone 60 mg orally once daily for 5 days, then tapered by 10 mg each day until day 10, prednisolone 1 mg/kg/day for 10 days in children (only use in children if complete palsy).

In upper respiratory tract infections, oral or intranasal glucocorticoids accelerate the resolution of otitis media with effusion (Hussein et al., 2017) but do not improve the quality of life (Francis et al., 2018). According to the American Academy of Otolaryngology-Head and Neck Surgery (2016), oral or intranasal steroids should not be used in otitis media cases with effusion as no data confirms long-term benefits from this approach (Rosenfeld et al., 2016). Intranasal steroids are commonly used to treat acute rhinosinusitis, chronic rhinosinusitis, and chronic rhinosinusitis with nasal polyps to reduce the severity of symptoms (Rot et al., 2020; Mullol et al., 2009; Head et al., 2016). The European Position Paper On Rhinosinusitis and Nasal Polyps (EPOS 2020) does not support using intranasal glucocorticoids in acute rhinosinusitis (common cold) in adults or children. However, some benefits can be achieved when using in the post-viral phase of acute rhinosinusitis (moderate quality of data, strong evidence). Systemic glucocorticosteroids should not be prescribed in this condition due to EPOS guidelines as they do not impact recovery in 7–14 days. In chronic rhinosinusitis (CRS), intranasal glucocorticoids remain the mainstay of the treatment, reducing symptoms and improving quality of life. When the nasal polyps occur in the course of the CRS, treatment with intranasal steroids reduces polyps' size and prevents polyps' recurrence after surgery (high-quality evidence). It is still under debate if there is strong evidence to support oral corticoids in chronic rhinosinusitis. EPOS guidelines advise using oral glucocorticoids in 1–2 short courses per year as an addition to intranasal treatment, which can help reduce symptoms and nasal polyp score. In children with CRS, although there is no evidence of the efficacy of this intervention. However, considering its safety profile, it is recommended to use intranasal steroids as part of the treatment (Fokkens et al., 2020).

Topical corticoids are helpful in the short-term treatment of conjunctivitis. However, according to most guidelines, their use should be limited to severe cases. In addition, side effects of the therapy are prolonging adenoviral infections, worsening of HSV infection course, increased intraocular pressure, glaucoma, or cataracts. Thus, the steroid choice should be carefully evaluated if the benefits of the therapy outweigh the risks (Holland et al., 2019).

Colchicine

Colchicine is a drug commonly used to treat gout and Behcet's disease. The primary anti-inflammatory mechanism of action is based on tubulin disruption, which causes the downregulation of multiple inflammatory pathways (Leung et al., 2015). In addition, colchicine inhibits the migration and activation of neutrophils and interrupts mast cells degranulation (Dalbeth et al., 2014).

Some studies show that the use of colchicine may be helpful in infections treatment. There is some evidence that colchicine is beneficial in managing viral liver diseases and may reduce time to deterioration, hospitalization time, and mortality in patients with COVID-19. Some studies indicate potential therapeutic utility in treating malaria, anogenital warts caused by human papilloma-virus (*condyloma accuminata*), common warts (*verruca vulgaris*), viral myocarditis, and *erythema nodosum leprosum*. Unfortunately, there is also an increased risk of pneumonia in patients using colchicine (McEwan and Robinson, 2021).

Anti-inflammatory therapy for COVID-19

In the course of COVID-19 infection, the three phases were described. In the first phase of early infection, the virus infiltrates lung parenchyma cells. In the second phase, lung tissue injuries occur because the host activates an immune response against the pathogen. The last phase, called the inflammatory cascade ("*cytokine storm*"), is caused by pathogen patterns exposed during viral replication. In this part, we notice an excessive inflammatory response to SARS-CoV-2 infection with viral load not correlated with the worsening of symptoms. Signals created by the SARS-CoV-2 virus cause the assembly of a pro-inflammatory protein complex, which converts the pro-IL-1 β and pro-IL-18 to their active forms. IL-1 β drives the synthesis of IL-6, which induces C reactive protein (CRP) and is considered a major pro-inflammatory factor in the COVID-19 cytokine storm. IL-1 β and IL-6 activate neutrophils that infiltrate into the lungs and tissues of other organs. They degranulate and release more cytokines, chemokines, and proteases, causing inflammation of the affected organs, resulting in organ failure. Neutrophils also trigger events in arteries that promote thrombosis. Using anti-inflammatory drugs in the COVID-19 treatment is based on the idea to stop the activation of the cytokine storm (Reyes et al., 2021; The Recovery Collaborative Group, 2021).

Corticosteroids and immunomodulatory monoclonal antibodies are commonly used as anti-inflammatory drugs in the treatment of COVID-19 patients. In severely ill patients with COVID-19, systemic corticosteroids are strongly recommended because they result in lower mortality among patients receiving mechanical ventilation and among patients receiving oxygen

without mechanical ventilation. Patients without respiratory support did not benefit from taking corticosteroids (The Recovery Collaborative Group, 2021; Sterne et al., 2020). On the other hand, in adults with mild COVID-19, inhaled budesonide may lower the frequency of urgent care visits (Ramakrishnan et al., 2021). *Tocilizumab* is a monoclonal antibody blocking the interleukin-6 receptor. Studies have shown that in patients with severe COVID-19, *tocilizumab* improves survival (Abani et al., 2021; REMAP-CAP Investigators, 2021). Some studies also suggest that the use of colchicine may reduce the risk of hospitalization or death in patients with COVID-19 (Tardif et al., 2021).

Anti-inflammatory drugs are also used in Multisystem Inflammatory Syndrome in Children (MIS-C), a disease that is a complication following exposure to SARS-CoV-2 and had been announced first time by the Royal College of Pediatrics and Child Health (RCPCH) on May 1, 2020. This rare systemic inflammatory illness occurs mainly in children. It can lead to rapid multi-organ failure and the need for intensive care (Okarska-Napierała et al., 2020, 2021). In treating this disease, intravenous immunoglobulin, methylprednisolone, IL-1 antagonists, IL-6 receptor blockers, and anti-TNF agents are used (Harwood et al., 2021).

Conclusions

Anti-inflammatory medications are frequently used in infections to mitigate accompanying symptoms. They also act as host immune response modifiers and play an essential role in treating infections in selected groups of patients, e.g., with mucoviscidosis or COVID-19.

However, anti-inflammatory agents generally impair the immune system. NSAIDs inhibit granulocytes functions and enhance cytokines production, including TNF, and may contribute to the emergence of bacterial soft tissue infections or promote the development of the life-threatening disease from a minor infection, usually well-controlled by an immune system. Reducing infected patient's symptoms and signs of inflammation may provide a false sense of security and delay diagnosis of serious infections.

Historical background

The bursa of Fabricius stem from Hieronymus Fabricii (“Fabrizio”), born in 1533 in Acquapendente, nearby Rome, and died in Padua in 1619. In his work *De formatione pulli*, he described for the first time the presence of an organ near the cloaca, the “bursa of Fabricius.” Fabricii, did not find the bursa in the male bird, so he concluded that its function was just a receptacle of semen. The first evidence of the role of the bursa of Fabricius in the immune response was in the 1950s. In 1954, Bruce Glick at the “Ohio University,” was studying the effects of neonatal bursectomy on later chick development and he found that bursectomized chicks grew normally, according to the controls (Glick et al., 1956). One of Glick’s collaborators, named Chang, employed chicks while evaluating the antibody response, treating them with the O antigen of *Salmonellatyphi murium*. Six out of nine animals deceased instantaneously; two survived, despite no antibody response could be detected. Glick postulated that the early removal of the bursa was responsible for the loss of antibody formation capacity. As a matter of fact when the bursa was removed later, the modification of the antibody response was minimal or absent (Glick et al., 1956).

In 1961, both Francis A.P. Miller in London and Robert A. Good in Minnesota uncovered neonatal rat and rabbit thymectomy to drive a severe alteration of cell immunity, involving an altered ability of rejection of cutaneous and other tissues transplants (Miller, 1962; Papermaster et al., 1962). The US immunologist Max D. Cooper noted that also the people with Wiskott-Aldrich syndrome, an X-linked disease, developed viral herpes lesions associated with defective immunity with high levels of antibodies (Cooper et al., 1968). Conversely, children with agammaglobulinemia linked to hereditary immunodeficiency of chromosome X, controlled viral infections even though without an antibody response. He concluded that lymphocytes producing antibodies and the thymus-derived lymphocytes that led to rejection were different from each other (Cooper et al., 1968).

In 1963, Cooper, Good and Peterson, at the “University of Minnesota,” carried out experiments of neonatal chick bursectomy and thymectomy followed irradiation. After irradiation, the structure and function of their immune systems were examined. The treated animals deemed smaller, manifested a lack lymphocytes count and functions, both at a cellular and umoral level (Cooper et al., 1965).

In chickens infected with *Brucella abortus* bacteria and undergoing a bursa radiation, no antibodies were produced even if the internal thymus linked organs showed no infection. In this context, the bursa influenced the ability to produce antibodies, whereas it did not interfere with the development of cellular immunity. However a significant immune response deficiency marked the thymectomized animals. In brief animals subjected to bursectomy and thymectomy had a severe impairment of humoral and cellular immunity (Cooper et al., 1966).

The human equivalent of the bursa of Fabricius still represents an unmet scientific need. In 1974, by the use of fetal liver cell cultures, Cooper, who had moved to London in those years, and some of his colleagues at the “University College” of London found that these cells originated bone marrow (Cooper et al., 1974).

In 1952 on “Pediatrics” Ogden Bruton a primary physician at the “Walter Reed Army Center” reported an antibody immune response defect. He dealt with an eight-year-old child with a history of recurrent episodes of pneumococcal sepsis, such as pneumonia, purulent otitis media and septic arthritis, which had lasted 4 years. Remarkably, the serum electrophoresis showed a lack of gamma migrating globulins (Buckley, 1998). Before proceeding with the electrophoretic analysis, attempts had been made to control recurrent infections with chemo-, serum- and vaccine-therapy. Bruton also had the merit of trying for the first time the substitutive treatment with gamma-globulins that led to the child clear improvement so that he and the medical community were

able to have a normal growth in the following years in both primary (Hitzig, 2003) and secondary immunodeficiencies (Vacca et al., 2018). The report from Bruton unveiled that the clinical phenotype could be due to either an inborn or to an acquired deficiency of the antibody assembly mechanism. In actual fact, the case described by Bruton was not a congenital sex linked agammaglobulinemia or Bruton type because the histological examination of the tonsils, bone marrow and liver showed that the structure of these organs was normal. The Bruton disease or X-recessive agammaglobulinemia comprises in an acquired X-linked inborn error of immunity, categorized by a lack of immunoglobulins production. The driver event is due to a gene mutation of the Bruton tyrosine kinase (BTK), characterized by a defect of B lymphocytes maturation. The children affected by Bruton type-agammaglobulinemia rarely get sick during the first 6 months of life, because they are covered by antibodies received from their mothers. The agammaglobulinemia syndrome case picture was characterized by serious recurrent infections (pneumonia, meningitis, sepsis, otitis, synovitis and conjunctivitis) associated with a marked *hypogammaglobulinemia*. These subjects exceeded the fungal and viral infections with relative effortlessness, instead of experience severe manifestations as a result of infections by pyogenic germs (Kornfeld et al., 1997).

In 1952, three types of agammaglobulinemia were described: (a) congenital, characterized by recurrent bacterial infections which occurred in male children either in childhood or in early puberty; (b) acquired, characterized by a series of serious recurrent infections which could occur starting from puberty throughout life; (c) transient, observed in early infancy, from the sixth-ninth month of life and which spontaneously regresses around 3 years of age, as a consequence of a defect in the autonomous synthesis of antibodies by the infant, who, in the first months of life after birth, is defended by immunoglobulins of maternal origin (Gitlin et al., 1956; Hitzig, 2003). In the same year it was also demonstrated that plasma cells were not present into the bone marrow of agammaglobulinemic patients and that antibodies were not synthesized in these patients following antigenic stimulation. Moreover, the lymph node germinal centers were absent and the tonsils hypotrophic. On the other hand, the T-dependent paracortical areas of the lymph nodes were normally developed and atrophic after antigenic stimulation. Finally, in the same year the case of a patient with a thymoma was described, showing in addition to low antibodies levels a reduced ability to reject allografts and to elaborate a delayed hypersensitivity response (Smith et al., 1994).

In 1968, Angelo M. Di George a pediatrician at "Temple University's School of Medicine," discovered that the children born without thymus presented few circulating lymphocytes and lacked immune cell functions, without any alteration of circulating antibodies and plasma cells, and showed an abnormal susceptibility to viral and fungal infections. In these children the development of epithelial anlagen derived from the third and fourth branchial pouches, which give rise to the thymus during embryonic development didn't occur. Additionally, the cells arising from neural crest contribute to the thymic epithelial anlagen formation and the lack of their migration leads to a defect in the thymus development and reduction of T lymphocytes. From the third branchial pouch originates also the mandible, the two superior parathyroids, the cone and the trunk of pulmonary artery and the origin of aorta. Thus, in the Di George syndrome there are variable combinations of defects in the development of parathyroids, the thymus, the arterial cone of the pulmonary artery, the ascending aorta and the aortic arch, as well as craniofacial anomalies (Kirkpatrick and DiGeorge, 1968).

Inborn errors of immunity overview

Inborn errors of immunity associated with immune dysregulation comprise three major cohorts of inborn errors of immunity that often associate or even predominantly manifest with immune dysregulation. They are autoimmune-lymphoproliferative syndrome- (ALPS-) like disorders, typically characterized by autoimmune cytopenia and lymphadenopathy; Conversely, IPEX-like diseases are typically present with enteropathy, type I diabetes, thyroiditis. Arthritis, eczema and vasculitis; moreover, common variable immunodeficiency disease- (CVID-) like diseases are rather characterized not only by hypogammaglobulinemia, recurrent infections, but also, even at presentation, by immune cytopenia in particular idiopathic thrombocytopenia (ITP) (Chandrakasan et al., 2019). The antibody deficiency represents an *archetype* of B cell failure, being a mix between the agammaglobulinemia phenotype, as well as the phenotype of the IgA and IgG2 subclass deficiency and the isolated IgA deficiency (Oxelius et al., 1981; Tuijnburg et al., 2018; Yazdani et al., 2017). The Inborn Errors of Immunity Committee (IUIS) classified these disorders (Tangye et al., 2020), acknowledging that B cell defects are included, although being not limited to diseases like agammaglobulinemia and CVID population where B cells are not functioning correctly either because they are not producing any gamma globulin at all or in the case of certain amounts of antibody which are insufficient to cope with the entire immunological repertoire (Table 1).

CVID is one of the most characteristic disorders in which the autoimmunity, the lymphadenopathy, the splenomegaly and the neoplastic proliferation intersect, which sheds more light onto the multisystem involvement in terms of interstitial lung disease and gastroenteric manifestations. Remarkably, low serum immunoglobulin G (IgG) and with a marked decrease of at least two standard deviations below the mean for age, usually almost always also IgA and or IgM isotypes reduction are detectable (Wang and Cunningham-Rundles, 2005). Basically, the onset of immunodeficiency is to the fullest at 2 years of age, with a lack of isohemagglutinins and poor response to vaccines, after having excluded alternative defined causes of hypogammaglobulinemia (Bonilla et al., 2016). Any age can be interested, although gender can represent a major difference, with an earlier onset among males compared to females (median age of diagnosis 36 vs. 25, for females vs. males respectively) (Cunningham-Rundles, 2019; Odnoletkova et al., 2018), therefore it is not necessarily a pediatric illness. There is a failure of the development of plasma cells looking at the gastrointestinal tract or in the bone marrow of the CVID patients who have a great paucity of plasma cells in the bone marrow and the same behavior appears in the gastrointestinal tract, along with low IgA levels., conversely in the case of

Table 1 IUIS classification of primary immunodeficiencies.

1. Immunodeficiencies affecting humoral and cellular immunity
2. Combined immunodeficiencies with associated or syndromic features
3. Predominantly antibody deficiencies
Severe reduction in all serum immunoglobulin isotypes (agammaglobulinemia)
Severe reduction in at least 2 serum immunoglobulin isotypes with low or normal B cells (CVID)
Severe reduction in IgG and IgA with normal/elevated IgM
Isotype, light chain, with normal number of B cells
4. Diseases of Immune dysregulation
5. Congenital defects of phagocyte number or function
6. Defects in intrinsic and innate immunity
7. Auto-inflammatory disorders
8. Complement deficiencies
9. Bone marrow failure syndromes
10. Phenocopies of inborn errors of immunity

inflammatory bowel disease a plethora of immune cells infiltrate the gastrointestinal tract (Daniels et al., 2007). B cells are predominantly in germ-line configuration, paralleling the lack of plasma cells (Roskin et al., 2015), with very poor somatic mutation, thus, the B cell receptor if you sequence it has really made no attempt at adaptation to the environment and patients with very low isotype switched memory B cells have almost none whatsoever and those who have slightly more immunoglobulin have just an attempt at some somatic hypermutation (Roskin et al., 2015). Therefore, the B cells are actually incapable of responding to the environment. We examined several approaches to confront the available evidences and three key points emerged.

Immunodeficiencies affecting humoral and cellular immunity

B-cell immunity is one of the leading causes of inborn errors of immunity, determining antibody disorders. Dissecting the mechanisms beyond bone marrow a B-cell differentiation occurs. In the early phase, a cell commitment to lymphoid progenitor is taking place and during this phase there are important transcription factors involved such as Ikaros, E2A, ILR7 and PAX5 which are necessary to define certain key transcriptional programs (Pongubala et al., 2008, p. 5). At this stage a lymphoid progenitor can still become an NK- or T-cell, however PAX5 is a B-cell commitment factor and, when expressed, the lymphoid progenitor can move on in the B-cell lineage differentiation and V-DJ recombination process (Nutt and Kee, 2007), necessary to form the B-cell receptor (BCR). The first phase is the formation of the pre-BCR, constituted by the heavy chain, during which V, D and J are randomly recombined prompting the expression of an heavy chain and a surrogate light chain (Löffert et al., 1996). This passage is crucial for the first checkpoint happening in the Pre-BII stage (Mårtensson et al., 2010). The preBCR signaling is pivotal not only for light chains rearrangements, proliferation initiation and termination (Löffert et al., 1996; Mårtensson et al., 2010), but also for mutations in BTK (XLA) or IGM, CD79a/b, BLNK, L14.1 or PI3Kalpha (AR) (Abolhassani et al., 2019). Conversely, the mutations in TCF3 (E47) (Boisson et al., 2013) Ikaros (Kuehn et al., 2016) and Pax5, being early b-cell defects, constitute a new category of early B-cell deficiencies due to mutation in early transcription factors. In more details Boisson et al. reported about four patients with the same de novo mutation in TCF3 gene, in a hotspot of the BASIC domain (Boisson et al., 2013). Therefore, a mutant protein expressed in the nucleus exerts a dominant negative effect when bound to wild type E47 as homodimer, leading to isolated agammaglobulinemia with decreased number of peripheral B-cells. Of note, on CD19^{pos} B-cell BCR was lacking, thus the authors deduced that E47 plays a critical role in enforcing the clock of precursor B-cells without a functional BCR, indicating a new role of E47. The TCF3 autosomal recessive form, constituted by an homozygous TCF3 mutation, has been associated with severe hypogammaglobulinemia and B-cell acute lymphoblastic leukemia (Ben-Ali et al., 2017). In this case the TCF3 mutation has been uncovered to drive E2A protein absence via a nonsense mediated decay; nonetheless HEB might functionally compensate for E2A loss as some CD19^{pos} B-cells are present (Ben-Ali et al., 2017). The first case-series available on IKAROS (IKZF1) autosomal dominant mutations reported a progressive loss of immunoglobulins and B-cell on 26 patients from 6 families (Kuehn et al., 2016). Interestingly, Kuehn et al. not only found a clinical variability but some asymptomatic patients developed an acute lymphoblastic leukemia (Kuehn et al., 2016). The reported mutations were missense mutations or deletions, which still allowed a stable protein that although still able to dimerize, is unable to bind target DNA, in a haploinsufficiency and incomplete penetrance clinical phenotype (Kuehn et al., 2016). The clinical spectrum of IKAROS deficiency is broad, with germline heterozygous mutations associated with a severe immunodeficiency that progresses to T-cell acute lymphoblastic leukemia (Yoshida et al., 2017). Moreover, germline heterozygous IKAROS mutations can cause dysgammaglobulinemia, hematologic abnormalities, including B-cell defects and autoimmune diseases (Hoshino et al., 2017; Van Nieuwenhove et al., 2018). Dominant-negative IKZF1 mutations can also cause a T, B and myeloid cell combined immunodeficiency (Boutboul et al., 2018). Dominant negative IKAROS mutations cause a defect in T cells composition, with naïve but neither effector nor memory T cells present and *Pneumocystis jirovecii* pneumonia, demonstrating a defect involving functional T cells (Boutboul et al., 2018). Myeloid defects were also reported (i.e., myeloid-derived dendritic cells).

This disease phenotype demonstrates that IKAROS not only cause a B-cell development but play a broader role (Boutboul et al., 2018). Of note, the definition of main precursor B-cell populations comprises the existence of Pro-B, Pre-B-I, Pre-B-II, Immature and mature cells depending on TdT, CD19, IgM, cytg, and IgD expression detected at FACS (Wentink et al., 2019). The above-mentioned is a heterogeneous rather than a homogeneous population: while considering the expression of TdT and CD34, it is possible to distinguish two different cell types within the Pre-B-I and Pre-B-II cells; those data have also been confirmed by single-cell-RNAseq data, which showed a gradual expression of CD20 (Solimando et al., 2016; Wentink, 2018) from Pre-B-I and Pre-B-II cells and multiple differentiation trajectory. Thus, the precursor B-cell differentiation is not linear and not fully elucidated.

From the peripheral B cell differentiation standpoint, the antigen recognition and cell-signaling are of paramount importance and dependent on the CD19, CD21 and CD81 complex; thus, a mutation in one of these complexes leads to a block in the differentiation process and an incomplete activation of B-cells (Levy et al., 1998; van Zelm et al., 2010). In the spleen and MALT the T-cell independent differentiation and the T-cell-dependent differentiation in the lymph nodes and in the peripheral lymphoid organs, are also crucial (Arjunaraja et al., 2017; Herlands et al., 2008). The fundamental B/T-cell interaction is necessary for further differentiation and somatic hypermutation in the variable domains and improve the specificity of the immunoglobulins and the class switch (Arjunaraja et al., 2017; Herlands et al., 2008; Wentink, 2018). Many genetic defects have been defined in the B-cell differentiation (Bousfiha et al., 2018). Focusing on the class switch and recombination inborn errors, based on the immunological function it is possible to distinguish defects in T-cell-B-cell cooperation, intrinsic B-cell defects and DNA repair defects. Regarding the first group, CD40/CD40L, NEMO and T_{FH} defect share common complications, such as opportunistic infections, liver damage and autoimmunity. Within the intrinsic B-cell defect subgroup, damages in the enzyme machinery modulating somatic hypermutation, such as AID and AID co-factor mutations lead to lymphadenopathies and autoimmunity. Conversely, patients with defects in DNA repair can be affected by autoimmunity, B cell lymphomas, leukemias cancers and neurological deterioration (Bousfiha et al., 2018; Solimando et al., 2020). In more details, subjects with UNG deficiency develop a susceptibility to bacterial infections of the respiratory tract, cervical and mediastinal lymph node hyperplasia, increased serum IgM and decreased serum IgG and IgA concentration (Tesch et al., 2018). Moreover, constitutional mismatch repair deficiency (CMMRD), such as AR mutations in PMS2, MHL1, MSH2 and MSH6 determine cancer predisposition syndromes, comprising hematologic malignancies, brain tumors, colorectal and intestinal malignancies and other cancers such as embryonic tumors and rhabdomyosarcoma (Tesch et al., 2018). Of note, those subjects can have no clinical signs of immunodeficiency and no uniform abnormalities. Often this group of patients has a reduced level of somatic hypermutation (IJspeert et al., 2017) and uracil-DNA-glycosylase (UNG) is involved in generating GC transversion. Conversely the patients with MSH2 and MSH6 mutations, are affected by AT mutations (IJspeert et al., 2017). Furthermore, MMR deficiency leads to less mutation at POLH motifs, while MMR deficiency leads to more mutations at AID motifs (IJspeert et al., 2017). As a consequence, it is possible to envision a 5-pathway model for somatic hypermutation in human in which AID induces somatic mutations in variable genes, often immunoglobulins, and these lesions can be resolved in five different ways, namely by replication, short-patch BER, long-patch BER, MMR and hybrid pathway (IJspeert et al., 2017). Thus, this knowledge has also been translated in a somatic hypermutation analysis in CVID (van Schouwenburg et al., 2018), combining the flow cytometry, the histopathology and the repertoire analysis dissecting the irregular shape of the patient's lymph nodes with reduction in B cells, decreasing SHM, as well as disturbances in antigen selection and class recombination (Unger et al., 2018). Therefore, as they ensue monogenic and polygenic defects, transcriptome and epigenetics cooperate in driving the inborn errors of immunity (Kienzler et al., 2017).

Combined immunodeficiencies with associated or syndromic features

CVID is multifaced, being clinically and molecularly heterogeneous. The immunopathogenesis is characterized by a B cell maturation defect, leading to a decreased B cell memory phenotype, coexisting with poor T cell proliferation along with expansion of immune lymphoid cells (ILCs) and impaired dendritic cell differentiation, TLR 7/9 defects and IFN alpha signature (Bonhomme et al., 2000; Cols et al., 2016; Grimbacher et al., 2003). A whole exome sequencing (WES) uncovered several monogenic causes (Bogaert et al., 2016), nonetheless, several modifying genes and combination of single variants are involved, therefore the heterogeneity and the attempts to subset CVID patients are aiming to linking the genetic defect to the resulting clinical phenotype as well as the immune function. To this end, a plethora of scientific productions combined WES data and single-cell immune phenotypic and functional data. The subcategorization of CVID patients which passed on their immune phenotypic and functional defect mass cytometry (CyTOF) single-cell high dimensionality, allowed to screen up to 50 rare-earth elemental mass channels, combining phenotypic and functional measurements. Focusing on innate immunity (Mills, 2011), it is possible to assess the activation of innate response, by sketching the phosphorylation of cell protein via phospho-flow cytometry. Conversely, in order to thoroughly decipher the adaptive immunity counterpart, investigators engaged TCR and BCR signaling both proximal, such as Zap70, LAT and PLC1 and downstream, while looking at more distal signaling protein such as ERK1/2, s6, pAkt, pCREB and p38MAPK (Bendall et al., 2011; Hsieh and Hernandez, 2016).

Defects in intrinsic and innate immunity

Dealing with innate immunity and defense against virus infections, we recognize cell-extrinsic and cell-autonomous factors playing a major role in anti-viral defenses (Lehnardt et al., 2003; Man and Kanneganti, 2016). Among the cell-extrinsic mechanisms, NK

cells, type I and III IFN and inflammatory cytokines are mostly involved; contrariwise autophagy, restriction factors and cell death share the most relevant cell-autonomous physiopathology (Lehnardt et al., 2003; Man and Kanneganti, 2016). Virus recognition and induction of inflammatory and antiviral responses are mainly involved during viral infections, when a number of pattern recognition receptors on the cell-outside and at a cytoplasmic level recognize pathogens associated molecular patterns (Crotty, 2014). In the cases of virus nucleic acids, such as RNA and DNA a number of adaptive molecules ultimately signaling effectors such as NF- κ B and IRF factors implying antiviral IFN responses are induced. Additionally, inflammatory IL1 β -mediated responses, autophagy and death pathways boost the antiviral effectors repertoire (Balachandran and Beg, 2011). DNA sensors also play a pivotal role in driving the production and induction of type I interferon (Carter-Timofte et al., 2018b). Moreover, type I and III IFN signaling induce a broad range of IFN stimulated genes, restricting viral replication and promoting inflammation, while hampering leukocyte recruitment, activation and proliferation (Fensterl and Sen, 2009). The role of innate immune system in antiviral defenses emerged from evidence obtained from the knowledge of such defects as in IFN induction, actions (Carter-Timofte et al., 2019, p.; Mørk et al., 2015) and NK cell defects (Orange, 2002). Infact, TLR3 pathway defects, have been associated to herpes simplex encephalitis (Mørk et al., 2015), RNA POL III mutations, associated to severe VZV disease (Carter-Timofte et al., 2019) while MDA5 defects correlate with recurrent rhinovirus and severe RSV infections (Wang et al., 2011); furthermore, IRF7 is also associated with severe influenza (Jørgensen et al., 2018). Downstream of the IFN receptor signaling, the defects in IFNAR or STAT2 constitute an archetype for disseminated reactions to measles (Duncan et al., 2015; Hahm et al., 2005; Hambleton et al., 2013; Hernandez et al., 2019). Herpes virus infections are rather correlated to NK cell defects (Mace and Orange, 2019; Orange, 2002). Herpes simplex encephalitis is the classical starting point for deciphering the inborn error of immunity predisposing to viral infections by dissecting the role of defective IFN production downstream of TLR3 signaling in herpes encephalitis (Herman et al., 2012). Errors in double strand RNA lead to impaired type I IFN signaling in the brain hence increasing the incidence of herpes CNS infections in children (Lim et al., 2014). IRF3 deficiency mimics the aggressive viral infection phenotype, by inducing encephalitis (Andersen et al., 2015). Varicella-zoster virus infection differs from HSV CNS infection, being characterized by a predominant vasculopathy or vasculitis (Gilden et al., 2009). The underlying mechanism can be only partially elucidated by the role played by interferon and NK cells in preventing viremia, since T cells seem to orchestrate latency. However, IFN role in the reactivation is still unknown (Kinchington et al., 2012; Yewdell and Hill, 2002). A plethora of primary immunodeficiencies predispose to VZV infection (Biron et al., 1989; Brooks et al., 1990; Hsu et al., 2011; Wiegering et al., 2011) with translational theragnostic consequences (Dobbs et al., 2015; Kreins et al., 2015; Roesler et al., 1999; Zhang et al., 2009), often associated with severe bacterial and fungal infections. Remarkably, RNA polymerase III (POL III) has been uncovered to be a gatekeeper to prevent aggressive CNS viral-induced diseases (Carter-Timofte et al., 2018b). POL III provides immunological DNA sensing and drives the transcriptions of housekeeping genes at nuclear level; moreover, in the cytosol POL III may act as an innate-immune sensor of DNA, recognizing nucleic acid and regulating IFN responses (Carter-Timofte et al., 2018b; Chiu et al., 2009). Of note, there is an association between POL III defects and human disease, since mutations in POLR3A and POLR3B encoding RNA polymerase III subunits cause an autosomal-recessive hypomyelinating leukoencephalopathy ((Saito et al., 2011). Furthermore, defects in POLR3A and POLR3B also cause hypomyelinating leukodystrophies with or without dental abnormalities, hypogonadotropic hypogonadism (Daoud et al., 2013) and 4H syndrome with vertebral anomalies (Muthusamy et al., 2015). Cerebellar atrophy and hypomyelination have also been reported by Daoud et al. (Daoud et al., 2013). Remarkably, patients peripheral blood mononuclear cells (PBMCs) with POL III mutations have impaired IFN beta production in response to Poly(dA:dT) DNA (Ogunjimi et al., 2017). Moreover, PBMCs exhibit a defective ability to control VZV replication and an inability to produce IFNs in response to viral infections (Ogunjimi et al., 2017). Mechanistically, an impaired production of immunostimulatory 5'ppp-RNA after transfection with adenine-thymine (AT)-rich DNA has been reported along with a reconstitution of IFN production and viral activity in PBMCs transfected with POLR3C (Ogunjimi et al., 2017). The reason why POL III defects hold a strong disease phenotype is due to the fact that cGAS is considered the main cytosolic DNA sensing in humans. Indeed, VZV immune sensing by cytosolic DNA sensors, warrants further investigation aiming to elucidate why cGAS cannot compensate for a POL III defect (Ogunjimi et al., 2017; Zahid et al., 2020). One tempting hypothesis related to localization of VZV in lymphocytes causing viremia is issues from POL III rather than from cGAS. Collectively, in pediatric cases a combined effect of high AT content of the VZV genome and low cGAS expression by blood cells lead to impaired VZV sensing and increased viral replication in POL III defect (Ogunjimi et al., 2017). Conversely, in adults, a viral reactivation can drive a CNS vasculitis, correlated by recurrent VZV infection (Carter-Timofte et al., 2018a). A POL III defect in monozygotic twins with CNS vasculitis paradigmatically pinpoints the deleterious effects of the related decreased antiviral responses and increased VZV replication (Carter-Timofte et al., 2018a). In children POL III plays a role in IFN induction in an early phase of disease but the available clinical data point toward a POL III role in the maintenance of latency given the reactivation of disease in adults caused by VZV. Finally, the cGAS-STING pathway seems to be important in controlling VZV infection in the skin and in keratinocytes where cGAS is highly expressed. Viruses can be therefore recognized by several immune receptors, such as POL III, cGAS, TLR9, TCR, inducing a type I IFN response and halting viral replication via Th1 immunity. Thus, the effects on latency establishment and reactivation are also impacted by the immune response (Carter-Timofte et al., 2018b). There are still scanty data regarding VZV and innate sensing in terms of differences in pathogenesis, cell types and mechanisms involved in primary VZV infection compared to VZV reactivation. Additionally, differences in the genetic background might influence VZV encephalitis and vasculitis, hence the need of prompting further investigation regarding the role of POL III in innate sensing of VZV reactivation and priming of adaptive immunity. Whether additional biological determinants of innate or adaptive immunodeficiencies predisposing to VZV CNS infection exist remain to be elucidated.

The role of DNA sensing in defense and disease is also highlighted by the overproduction of IFN response in diseases such as SAVI – STING gain of function mutations (König et al., 2017) as well as Aicardi-Goutières syndrome due to Trex1 loss of function mutations (Crow et al., 2006).

Paradigmatic clinical manifestations

Remarkably, the data derived from a French cohort of patients with primary immunodeficiencies analyzed 2183 patients, detecting various forms of immunodeficiencies that develop immune dysregulation manifestation overtime, including common variable immunodeficiency patients (CVID) in green you have the combined immunodeficiency patients (CID) along with innate inborn errors of immunities (Fischer et al., 2017). Combined immunodeficiency and innate immunity defects present symptoms earlier in life and CVID patients harbor immune dysregulation manifestations, but in all cases a very high proportion up to 50–60% of patients develop immune-deregulation during the course of their disease. Infections dominate the clinical picture, nonetheless, more complicated patients can present autoimmunity, unexplained lung disease, with pulmonary infiltration, lymphoid hyperplasia, splenomegaly gastrointestinal enteropathy, liver diseases and granulomatous diseases (Resnick et al., 2012). People who have the complications have increased mortality over a period of about four decades (Resnick et al., 2012) Lymphoma for example and hepatitis and lung disease or malabsorption and gastrointestinal disease will shorten the lifespan.

Enlarged spleen is found in 20% of patients and sometimes can be massively enlarged with hepatomegaly (Agarwal and Cunningham-Rundles, 2019). Indeed, liver can also be interested, especially in CVID patients. A nodular regenerative hyperplasia associated with portal hypertension can happen. Nodular regenerative hyperplasia (NRH) is characterized by a widespread benign transformation of the hepatic parenchyma into small regenerative nodules with fibrosis, leading to portal hypertension, splenomegaly and significant thrombocytopenia (Ward et al., 2008), autoimmune phenomena that can easily be triggered by the unleashed immune system or immunecheckpoint pathway defect (Anquetil et al., 2018; Argentiero et al., 2020). Lymphomas represent a major concern during CVID natural history (Mellemkjaer et al., 2002), and the lymph architecture of a patient with CVID is not particularly easy to distinguish from the lymphomatous one (Nicolae et al., 2015). The USIDNET registry reported lymphoma to be increased in proportion with a few other tumors (Leone et al., 2018; Mayor et al., 2018). The interstitial lung disease and the lymphocytic granulomatous lung disease look, with ectopic germinal centers (Maglione et al., 2014) are clinical picture which would require B-cell depletion or chemotherapy since the lung pathology often contains CD3^{pos} T cells along with CD20^{pos} cells (Maglione et al., 2014).

Interstitial lung disease in common variable immunodeficiency is a major complication with a still unknown immune-pathology, in which it is clear that granulomatous-lymphocytic interstitial lung diseases (GLILD) represent a collection of heterogeneous entities (Park and Levinson, 2010; Verma et al., 2015) in which a pathogen might be involved in triggering this disease. Thus, GLILD represents a distinct clinic-radio-pathological ILD occurring in patients with CVID, associated with a lymphocytic infiltrate and/or granuloma in the lung, and also in all those whose conditions were checked and, where possible, excluded (Verma et al., 2015). In 29/34 GLILD was diagnosed after CVID (7.8. years; 98% CI 5.8–9.9) and in 5/35 simultaneously (Mannina et al., 2016). Laboratory and clinical biomarkers of ILD involve autoimmune cytopenias, persistent lymphadenopathy, splenomegaly, increased isotype-switched memory B cells, increased CD4/CD8 T-cell ratio in the blood and enhanced IgM concentration (Schussler et al., 2016). An association of immune dysregulation and arthritis has also been confirmed by Mannina et al. In 52 subjects, 26 of whom with GLILD. Hartono et al. uncovered splenomegaly, history of immune-mediated cytopenias, low serum IgA level, and percentage expansion of CD21^{low} B cells as useful tool to identify a group of patients at high risk for developing GLILD (Hartono et al., 2017). Retrospective data confirmed these findings (Gathmann et al., 2014; Malphettes et al., 2009; Quinti and Pulvirenti, 2017; Wehr et al., 2008). While looking at the B cell phenotype, very often CD21^{low} B cells in the interstitial lung disease patients, at both peripheral blood and broncho-alveolar lavage were detected; moreover, many patients had reduced percentages of CD4 T cells (von Spee-Mayer et al., 2019). Furthermore, there is an association between the levels of immunoglobulin level and need to treat, especially in terms of IgM levels, most likely due to an immune overactivation (Schussler et al., 2016). Ancillary, there is the soluble IL2 receptor (sIL2R) levels are elevated in nearly all ILD patients (Vitale et al., 2015). From a histopathological standpoint Mannina et al. showed no significant differences in biopsy-proven and non-biopsy-proven ILD patients (Mannina et al., 2016) plus the ones treated based on the CT appearance. It is clear that most often bronchial biopsies can miss the diagnosis (Mannina et al., 2016; Schussler et al., 2016). The bronchoalveolar lavage differential cell count might support the imaging findings (Mannina et al., 2016), often detecting signs of inflammation, constituted by a mixture of lymphocytes, comprising CD21^{low} B cells, when compared to sarcoidosis (Mannina et al., 2016). Nonetheless, the underlying pathomechanisms are largely unknown. Remarkably in retrospective survey-based patients records pulmonary function testing seems also to serve as a promising diagnostic tool (Akhter et al., 2018; Jolles et al., 2017b); nonetheless, there is a lack of high quality and level of evidence and the indication to perform the bronchoalveolar lavage in PID subjects annually, can be a suggestion (Akhter et al., 2018; Jolles et al., 2017b); addressing lung function is also remarkable how normal tests can coexist with heavy changes in the CT scan. In more details, normal lung function does not exclude GLILD and an isolated impairment of DL_{CO} has also been reported (Akhter et al., 2018; Jolles et al., 2017b); however, DL_{CO} can vary largely, thus the decision for need of interstitial lung disease screening is made by additional aspects, often based on the clinical judgment. Of note lung function can worsen over time, especially in terms of lung diffusion capacity, pointing toward the relevance of careful follow up and, possibly, early biomarker of lung impairment (Meerburg et al., 2020). Remarkably, lung function tests can be expressed as absolute and percentage of predictive

value, corrected for age, sex, height and race; the percentage of predicted value however does not decline with age because it is corrected according to age. Usually, the definition of abnormality during interpretation of lung function arbitrarily refers to <80% of the predicted value, but change is more important. Moreover, how to quantify symptoms and the reliability of data obtained from patients with low lung function remain unmet clinical needs. In order to address these issues, Hurst et al. reported that the preferred measure of treatment response employed is the change in gas transfer (DL_{CO} and K_{CO}), with no complete consensus regarding the threshold of change thought to be significant: 10–20% for 63% of 19 respondents in the study vs. 21% who considered a change of 20–30% significant (Hurst et al., 2017). Dealing with quantifications of symptoms, breathlessness represents an archetypic complaint being quantified, either by MRC and mMRC, (Chhabra et al., 2009; Hajiro et al., 1998; Henoch et al., 2016; Mahler and Wells, 1988); Borg (Kendrick et al., 2000) or TDI/BDI (Mahler et al., 1995) scores. The MRC and mMRC scores main limitation is the lack of sensitivity for changes. Borg scale strength is its easier applicability. The TDI/BDI scale include other variables such as functional impairment, the magnitude of task and the magnitude of effort, being probably one of the most holistic scales (Cazzola et al., 2008). Moreover, to assess cough, the Leicester Cough Questionnaire (Birring et al., 2003) a worthy tool for clinical trial, despite a partial deficiency of practical applicability, while assessing objective responses. From the functional tests standpoint, the 6-min/incremental shuttle walk (Enright, 2003; Parreira et al., 2014) suits a relevant patient's need aiming to optimizing the accountability of given interventions in every-day-life.

The CT parameter changes that can support the clinical decision-making highlight how much GLILD encompasses different granulomatous, lymphoid (i.e., lymphoid hyperplasia, follicular bronchiolitis, lymphocytic interstitial lung disease-LIP), inflammatory lesions (i.e., organizing pneumonia-OP). In a few patients reticular patterns resembling non-specific interstitial pneumonitis-NSIP with a stronger reticular pattern can also be present (Cereser et al., 2017). Thus, difficulties in comparative analysis of CT scans warrants future consensus and guidelines. Computer program would probably provide quantitative support in decision making (Schütz et al., 2019). Ground glass and number of nodules are the imaging findings more often considered in the careful risk stratification; in the absence of ground glass changes all severities of number of nodules can be found equally and ground glass changes without noduli is very rare, being ground glass severity parallel to many and larges nodules, most likely (Cereser et al., 2017; Meerburg et al., 2020; Schütz et al., 2019). Over time spontaneous alterations in ground glass number and size of nodules characteristically worsen, nonetheless, a variety of patients pinpoint the disease heterogeneity and the need to dissect the subgroup better, in order to more efficiently tailor the clinical decisions. The radioprotection represents a major concern; therefore, MRI has been considered (Milito et al., 2015). MRI sequencing can provide information regarding edema and cellularity of single nodules. PET CT is also a tool that can support follow-up, although the metabolic activity holds a lack of specificity (Jolles et al., 2017a), potentially threatening the evidence-based level to support the radio-exposure. Indeed, on one hand, chest X-ray is probably too insensitive compared to CT scan, whose approximate radiation dose is conversely a multiple of baseline annual exposure. PET-CT also deserves to be mentioned in terms of its potential role in providing activity information, while compensating a significant radio-exposure level with functional details, also useful in performing differential diagnose and response to treatment (Jolles et al., 2017a).

Looking at the relative risk of developing autoimmune manifestations in the cohort of patients with immunodeficiencies this risk is significantly higher than in the general population and it is in fact even 830-fold higher for the autoimmune hemolytic anemia than in the general population, 120-fold higher in general for the immune-cytopenia or other forms of cytopenias than in the general population (Fischer et al., 2017). Thus, obviously hematological manifestations are a very significant manifestation of this disorder.

Immunocheckpoint as critical regulator of immune responses

In the last few years new genetic defects have hampered the knowledge of the biological architecture beyond the phenotype of the inborn error of immunity. CTLA4 is a critical regulator of T cell responses, as a molecule that is expressed by activated T cells and it outcompetes CD28 which is a costimulatory molecule of T cells for T cell activation. CTLA4 has a higher affinity than CD28 and CD86, which are molecules expressed by antigen presenting cells (Walker and Sansom, 2015); when T cells expressing CTLA4 bind CD80 and CD86 shutting off the signaling that is normally provided by the CD28 activating molecule so dampening the T-cell responses. Moreover, CTLA4 is expressed by regulatory T cells, playing a critical role for regular T cell function and finally CTLA4 not only binds CD80 or CD86 but it also mediates trans endocytosis of these molecules, basically stripping the antigen presenting cells of these molecules (Walker and Sansom, 2015), therefore, they can no longer function as professional antigen presenting cells, because they are unable to deliver the second signal, which is critically required for T cell activation. Thus, by a variety of mechanisms CTLA4 plays a major role in T cell regulation. The first paradigmatic condition representing a poster child for CTLA4 role in immunodeficiencies has been identified a few years ago as CTLA4 haploinsufficiency (Kuehn et al., 2014, p. 4; Schubert et al., 2014). The manifestations of these diseases include progressive lung disease with bronchiectasis and lymphocytic infiltrates, lymphoid aggregates in the central nervous system (CNS), lymphadenopathy and infiltration of lymphocytes in mucosal tissues, autoimmune cytopenias, hypogammaglobulinemia, T cell lymphopenia with presence of activated T cells. Because of the haploinsufficiency the disease is autosomal dominant in terms of inheritance, but it in actual facts has an incomplete penetrance. Data obtained from 96 patients recorded by Uzel et al. show a variable frequency of main manifestations of the CTLA4 haploinsufficiency about 50% of the patients had organ lymphocytic infiltrates and hypogammaglobulinemia, about 30% had evidence for neuroinflammation (Schindler et al., 2020), a significant proportion of patients reported recurrent infections (about 30%) and up to

35–40% of the subjects had been reported to have autoimmune cytopenias (Schindler et al., 2020). Remarkably, a variable percentage of subjects might be genetically affected but clinically asymptomatic individuals (Schindler et al., 2020), thus this disease may manifest at any age including elderly people and so these are people that are asymptomatic up to a certain time in their life, which doesn't mean that they will necessarily remain asymptomatic for their entire life (Schwab et al., 2018). A very similar picture is also shared by patients with LRBA deficiency which is an autosomal recessive disease also characterized by chronic lung disease and bronchiectasis, severe diarrhea with lymphocytic infiltrates, lymphoid interstitial pneumonia with predominant T infiltrates. Autoimmune cytopenias, hypogammaglobulinemia which is even more prominent than in CTLA4 deficiency, variable T cell lymphopenia with activated T cells, are perhaps more controversial infections in LRBA deficiency than CTLA4 deficiency as an autosomal recessive disease (Lo et al., 2016). LRBA acts as chaperon for CTLA4 and permits a recycling of CTLA4 which is internalized by the T cell and then can be re-expressed, thus, in the absence of LRBA CTLA4 is prompted to lysosomal degradation which results in significant reduction of CTLA4 levels on the surface. Therefore, patients with LRBA deficiency will have in fact low levels of CTLA4 on the cell surface pretty much like the patients with CTLA4 haploinsufficiency (Lo et al., 2016).

The spectrum of inborn errors of immunity and the concepts of autoimmunity and immunodeficiency in these disorders

The inborn error of immunity is characterized by more than four hundred single gene disorders of the immune system that drive the immunodeficiencies with infection susceptibility phenotype and those associated with immune-dysregulation which encompasses autoimmunity, lymphoproliferation and malignancies. The errors of immunity associated with autoimmunity, lymphoproliferation, bone marrow failure hemophagocytosis, parallel single genes disorders that present with this particular phenotype (Abraham, 2020).

The umbrella of immune dysregulation on one hand includes all the immunological and clinical manifestations (Fig. 1 and Table 2), although these clinical scenario is paralleled by a broad spectrum of specialties dealing with this particular disorder, namely hematologists, immunologists, rheumatologists, dermatologists, oncologists, lung specialists, hepatologists, gastroenterologists, pathologists, requiring a multidisciplinary approach to be effective.

Fig. 1 The extended spectrum of inborn errors of immunity. The knowledge of the immune dysregulation and infections related to primary immunodeficiencies and their underlying genetic disorders represent a continuum.

Table 2 Immune dysregulation and its clinical picture.*Immune dysregulation and its clinical picture*

Autoimmunity
 Autoinflammation
 Immunodeficiencies
 Lymphoproliferation
 Atopy
 Neoplasia
 Hyperinflammation
 Paraneoplastic syndromes
 Cytokine storm
 Lymphopenia
 Cytopenias

Table 3 Overview of the laboratory and clinical findings, correlated with the advanced diagnostic approach that can be implemented.

<i>Laboratory findings</i>	<i>Clinical findings</i>	<i>Advanced diagnostic approach</i>
Elevated inflammatory markers	Fever	Deep immunophenotyping
Hypo/Hyper-gammaglobulinemia	Rash	Assessment of T, B, NK cell and innate immune function
Elevated pro-inflammatory cytokines soluble biomarkers	Lymphadenopathy	Cytokine/soluble biomarkers
Cytopenias	Splenomegaly	Intracellular cytokines, proliferation
Autoantibodies	Cytopenias	NF-κB activation, TLR, JAK/STAT, PI3K and other signaling pathways
Quantitative alterations in lymphocyte subsets (lymphopenia/lymphocytosis)	Liver failure	Telomere length analysis
Functional abnormalities in adaptive and innate lymphocytes	Coagulopathy	Assessment of DNA repair pathways
	ILD	Genomics—Targeted WES, WGS, chromosomal arrays, SNP analysis, CNVs
	NLH of the gut/colitis	Analysis of VUS and functional validation
	Bone marrow failure	Transcriptomics and other OMICS

VUS, Variant of uncertain significance.

From the diagnosis standpoint of immune dysregulation clinical findings should be appropriately mixed with laboratory ones (Table 3).

Immunophenotyping, functional analysis and genomic analysis are essential in case of patients with inborn errors of immunity or immune dysregulation.

Therapeutic windows

In the retrospective analysis available concerning lung involvement across the immunodeficient patients, the most common approach across the demographic of treatment is to firstly approach subjects with interstitial lung diseases and immunodeficiency with steroids and as a second step, carry on with immunosuppressive therapies (Jolles et al., 2017b). Nonetheless, it is also evident that a subgroup of patients would need a more aggressive treatment as soon as possible. Indeed, starting with a glucocorticoid (GC) treatment leads to improvement of DLCO, but under GC treatment the course of DLCO is variable, with a tendency of further decrease in patients with a previous more severe impairment. Lung function testing shows characteristically variable degree of responses (Chase et al., 2013; Cinetto et al., 2021). There is also a mixed response in steroid treated patients in terms of groundglas, grade, number and size of nodules. GLILD is a discrete radio-pathological interstitial lung disease ensuing CVID course and correlates with lymphoid cells infiltration and with granulomatous reaction after having excluded alternative causes (Hurst et al., 2017). The aims of treatment in GLILD are the reduction of symptoms and preservation of lung integrity with reduced risk of death; however, the level of evidence is low (Hurst et al., 2017). Immunoglobulin replacement might be an option (Arish et al., 2006), therefore prompting validation studies regarding initiation and optimization of antibody replacement may be a solution. Some evidences from case series on 54 subjects on immunoglobulin pinpoint that GLILD changes may arise and progress in those on adequate immunoglobulin even if not on immunoglobulin (Arish et al., 2006; Gregersen et al., 2010). Moreover, optimization seems an appropriate strategy, although there is a lack of trials with higher dose immunoglobulin. Regarding the consensus level on decisions to start treatment, lung function deterioration seems to be the major driver of decision. Contrariwise, CT changes on their

own were not persuasive enough to start treatment (Hurst et al., 2017). When first treatment has been started 90% of participants in the trial lead by the British Lung Foundation/United Kingdom Primary Immunodeficiencies Network Consensus agreed that when was required, first-line should be corticosteroids alone. 20 out of the 21 respondents preferred to use oral prednisone (Hurst et al., 2017). minimum dose of 10 to 20 mg/day, maximum 1 to 2 mg/kg/day. The median (IQR) dose for a 70-kg patient was 40 (30–70) mg/day (Hurst et al., 2017). Some respondents used prednisone plus either azathioprine or mycophenolate as second agent (Hurst et al., 2017). The evidence for corticosteroids uses in GLILD are obtained from the French DEFI Study Group publication, where among 436 patients with CVID 13.5% were multisystemic granulomatous, with lung involvement in about 50% (Boursiquot et al., 2013). In this large case-series, 30–60 mg/day of GC brought a 54% response (Boursiquot et al., 2013). Nevertheless, evidential challenges of these observational studies are constituted by different definitions of disease, no definition of treatment response, different doses of different therapies and different monitoring regimens. Moreover, while assessing the treatment response, the test entity, its frequency and its inherent variation constitute pivotal issues. Second line therapy for GLILD can be considered in patients who responded to treatment and for those whose response to treatment needs a maintenance, while tapering the GC and, alternatively, it can also considered in subjects who did not respond to GC (Hurst et al., 2017). Azathioprine, rituximab and mycophenolate gained the highest consensus level in the special article by Hurst et al. (2017). In more details rituximab and azathioprine target B- and T-cells, respectively (Chase et al., 2013; Solimando et al., 2016). In the study from Chase et al. rituximab 375 mg/m² weekly was administered to 4/52 subjects and repeated monthly from four to six times (Chase et al., 2013). Azathioprine/6MP was typically administered at 1–2 mg/kg/day and mycophenolate 1 g, twice a day (Chase et al., 2013), with a background of immunoglobulin treatment, as in primary and secondary immunodeficiency (Pecoraro et al., 2019; Vacca et al., 2018). No infection concerns are reported and 5/7 patients responded in terms of radiological findings, the patients who did not respond had more severe restrictions and longer standing diseases (Chase et al., 2013).

Bone marrow transplantation has been performed in people with interstitial lung changes (ILD) not necessarily because of ILD (Wehr et al., 2015). Certainly, concerns in people survival deserves careful evaluation of mortality rate, especially in those patients who had a lung disease before transplantation.

Regarding the paradigmatic examples of inborn errors of immunity and given what happens in subjects with either CTLA4 haploinsufficiency or LRBA deficiency, an increased signaling through CD28 due to a lack of CTLA4 molecules on the cell surface takes place. This second signal allows the T cells to mediate activation of the AKT/mTOR pathway, prompting a lymphoproliferative syndrome (Westin, 2014), proangiogenic (Lamanuzzi et al., 2018) and autoimmunity (Koga et al., 2014). One way to counteract this phenotype is to provide the patients with a soluble CTLA4-Ig molecule, abatacept (Moreland et al., 2006) or belatacept (Wekerle and Grinyó, 2012), bind CD80 CD86 at high affinity, displaying CD28 and prompting blocking and hyperactivation of the AKT/mTOR pathway. Targeted therapies, by understanding the monogenic defect and intervening on that hold the promise to lead to CT changes (Lo et al., 2015). Results are not always as expected, given the poor response to abatacept in CTLA-4 deficiency, although a good response to abatacept in NF- κ B frameshift mutation has been reported (Verma et al., 2017). Alternative options are represented by mTOR inhibitors, able to inhibit lymphocytic infiltration and activation preventing autoimmunity (Suto and Karonitsch, 2020). For all of these disorders prospective clinical trials are still lacking, nonetheless as a consequence of retrospective studies looking at a phenotype in 133 patients, among the 14 who received either abatacept or belatacept 11 reported clinical improvement, in particular the clinical outcome was the improvement of enteropathy, the halting of lung lymphoproliferation, an improved platelet count and a reduced lymphadenopathy (Schwab et al., 2018). Thirteen patients received sirolimus, eight of them reported a good outcome with the resolution of transfusion dependent pure red cell aplasia regression of lymphadenopathy and splenomegaly, improved CMV viral load, enteropathy also improved in three patients who received sirolimus plus other immunosuppressive agents (Schwab et al., 2018). Statistically powered studies are absolutely needed in order to confirm these data. Another major pathway which may cause immune dysregulation with immunodeficiency is due to defects in the JAK-STAT signaling pathway, which is activated in response to a variety of cytokines and cytokine receptors (O'Shea et al., 2013). The extended clinical spectrum of STAT1 gain-of function mutations (Hambleton, 2016) in an autosomal recessive fashion, presents with very severe infections, with an early in life clinical feature and dominant negative phenotype, presenting with chronic mucocutaneous candidiasis, mycobacterial infection and other viral infections due to HSV, VZV, HPV, molluscum, cytopenias and other autoimmune manifestations, such as thyroiditis, alopecia and vitiligo, type 1 diabetes mellitus and systemic autoimmunity. Remarkably, STAT1 gain-of-function mutations are also related to some non-immune manifestations such as aneurysms, higher frequency of carcinoma and esophageal strictures (Yu et al., 2009, p. 3). Somewhat similar is the phenotype of the STAT3 gain-of-function mutations (Milner et al., 2015) in which enteropathy, lung nodules, lymphocytic infiltration of the respiratory tract and inflammatory lung disease predominate, along with alopecia, hypoparathyroidism, splenomegaly, type 1 diabetes and polyarthritis. Many of these subjects may have short stature (Milner et al., 2015). Collectively, pleiotropy and redundancy characterize JAK/STAT signaling pathway, but it also provides an opportunity to target these diseases by using specific molecules like JAK-inhibitors (Jamilloux et al., 2019) even though this drug specificity remains to be clarified (Patterson et al., 2014). Indeed JAK inhibitors are a novel class of drugs for targeted therapy in STAT1 and STAT3 gain-of-function (Forbes et al., 2018) that might be either pan-JAK inhibitors, such as oclacitinib (Gonzales et al., 2014), multi-JAK-inhibitors such as tofacitinib (Fleischmann et al., 2012), ruxolitinib (Verstovsek et al., 2012) and baricitinib (Richardson et al., 2020) or specific inhibitors, such as filgotinib (Vermeire et al., 2017), itacitinib (Schroeder et al., 2020), decernotinib (Fleischmann et al., 2015), still under investigation as an ideal molecule targeting the molecules that can allow a tailored treatment to ensue precision medicine available for these diseases.

The activated PI3-kinase delta syndrome (APDS) cell biology represents another paradigmatic example of inborn error of immunity. AS is a heterodimer composed by a kinase molecule, the p110-delta, and the regulatory molecule p85-alpha which

binds to p110-delta and prevents the catalytic activity of the p110-delta (Michalovich and Nejentsev, 2018). A heterozygous gain of function mutations on p110-delta or a loss of function mutations in p85-alpha, prevent the blocking activity on p110-delta and can result in phosphorylation of AKT with an induction of the mTORC1 in S6 phosphorylation. Therefore, in APDS an impaired FOXP3 expression and defective Treg function can parallel an increased aerobic glycolysis and lipid synthesis. Moreover, due to a direct effect via phosphorylation-mediated protein degradation on FOXO1, an inhibitor of cell survival and proliferation, the pervious biologic phenomena are unleashed (Cabrera-Ortega et al., 2017). Therefore, the clinical findings of patients with APDS are characterized by immune manifestations because of perturbed regulating cell function but also increased cell proliferation promoting generalized lymphadenopathy, with florid follicular hyperplasia, loss of germinal center cuff, defective Ig class switch and increased PD-1 positive T cells. Increased infection risks in particular due to CMV, EBV, VZV but also adenoviral infections are observed. Recurrent bacterial sinopulmonary infections are also reported as well as cytopenia due to autoimmune sequestration, Hodgkin and non-Hodgkin lymphoma, predominantly HBV positive however there also HBV negative cases (Coulter et al., 2017). PI3kinase inhibitors are available (Hoegenauer et al., 2017), such as specific inhibitor p110-delta, resulting in a significant reduction in the splenomegaly as well as a reduction in the biomarkers that characterize the immunological profile of these patients namely an increased proportion of PD-1 positive T cells and an increased, number of follicular helper T cells (Rao et al., 2017). Additionally IgM levels can undergo a significant decrease along with other immunoglobulin levels improvement (Rao et al., 2017). Another potential targeted therapy is based on PI3kinase inhibitor, nemoralisib, an inhaled PI3K inhibitor, potentially exerting a decreased effect on lymphoproliferation compared to leniolisib, due to the pharmacokinetics, nonetheless, patients with bronchiectasis and airway disease might primarily benefit from this approach (Nunes-Santos et al., 2019). Nemoralisib has also been used in patients with chronic obstructive pulmonary diseases and in a multicenter non-randomized open label uncontrolled single group study to evaluate the safety and pharmacokinetics of nemoralisib in patients with APDS (NCT02593539).

Regarding the treatment of immune-mediated cytopenias in the context of inborn errors of immunity, it is mandatory to understand that the hematological situation is often combined with an early onset of an inborn error of immunity per se and should prompt a differential diagnosis with an underlying hematological or autoimmune condition. Seldom, a reminiscent of GvHD can also be the primary cause. A large class of drugs can be categorized as shown in Table 4 (Seidel, 2020).

For autoimmune hemolytic anemia 15 trials are ongoing, exploring anti-FcRn (NCT03075878, NCT04119050), anti-SYK (NCT04138927, NCT03764618) anti-BTK (NCT04398459) and PI3K (NCT03538041). Moreover, a combination of B-cell depletion (Solimando et al., 2016) and novel drugs, such as rituximab and proteasome inhibition have also been intensively investigated (NCT04083014) (Ratnasingam et al., 2016). A complement inhibition has also been extensively explored (Berentsen and Sundic, 2015) (NCT02502903). Evans syndrome (Miano, 2016; Norton and Roberts, 2006; Stepensky et al., 2015) and immune thrombocytopenia (Feng et al., 2017a,b; Ghanima et al., 2021; Gómez-Almaguer, 2018; Newland et al., 2020; Ratnasingam et al., 2016; Ruzza et al., 2009); have also been broadly studied. Therefore, after having considered the underlying reason for the autoimmune cytopenia, including potential differential diagnosis (Seidel, 2020), recognizing the potential target for the primary cause is of paramount importance. Indeed, a gene product or an affected pathway could be directly druggable or even a related-pattern recognition can drive the overactive pathway involved targeting. Patients with CVID can represent additional challenge, when autoimmune neutropenia the use of GCSF or IVIG is still debated due to a lack of high quality and robust data. Nonetheless, the use of GCSF can be considered in a standby fashion, taking into account the patient history as well as the current and severity of bacterial and funga, with infection (Sokolic, 2013). High dose of IVIG might exert an immunosuppressive effect in patients with CVID, but there is a lack of evidence for its efficacy, despite case series and reports showed promising results in patients treated with high dose of immunoglobulin replacement therapy (Podjasek and Abraham, 2012). Nonetheless, patients with severe immune-mediated anemia and neutropenia should be probably considered for transplant, in order to avoid serious sequelae such as life-threatening infections, bronchiectasis and ILD (Teachey and Lambert, 2013). Antibiotic prophylaxis is also debated (Cunningham-Rundles, 2010).

Table 4 The classes of drugs for cytopenias in inborn error of immunity.

<i>The classes of drugs for cytopenias in inborn error of immunity</i>
Immune modulatory drugs (IVIG, anti-D, chloroquine, danazol, retinoids)
Growth factors (TRA; GCSF)
Targeted compounds (sirolimus, abatacept, idelalisib, complement-blockade)
Plasmapheresis
Immunosuppressive drugs (MMF, rituximab, CSA, fostamatinb, alemtuzumab, bortezomib, daratumumab)
Antiinflammatory drugs (glucocorticosteroids, anti-TNF α , anti-IL6, anti-IFN- γ , JAK-inhibits)
Splenectomy
Cytostatic chemotherapy
Allo-HSCT
Gene-therapy

A large number of anti-inflammatory drugs, immunosuppressive drugs, "targeted" drugs is not shown since they are overlapping. 6-MP, 6-mercaptopurine; anti-D, anti-Rh(D) antibody; AZT, azathioprine; CSA, cyclosporin A; CY, cyclophosphamide; GCSF, Granulocyte colony-stimulating factor; HSCT, Hematopoietic stem-cell transplantation; IFN- γ , interferon- γ ; IVIG, high-dose intravenous immunoglobulin G; JAK-inhibs, inhibitors of Janus kinases; MMF, mycophenolate mofetil; MTX, methotrexate; TNF α , tumor necrosis factor α ; TRA, thrombopoietin receptor agonists; VCR/VBL, vinca alkaloids.

State-of-the-art therapeutic approach: From transplant to novel insights

The cytopenia can be one of the factors that, when refractory, can prompt clinical decision regarding transplantation and gene therapy. Specifically, allogeneic hematopoietic stem cell transplantation (HSCT) in adults with primary immunodeficiency. The complexity of HSCT landscape is an emerging field, due to the difference between PID and typical adults transplant patients, constituted by disease- and patient-related factors. Firstly, genetic diagnosis frequently is lacking in adults presenting with PID, thus hematopoietic mutation is seldom demonstrated before transplant. Due to the rarity of the diseases themselves, often limited information on natural history of the disease in adulthood with conservative management alone are available, particularly, because only recently patients survive until the adulthood due to novel approaches and supportive care. Moreover phenotypical heterogeneity and atypical presentations still represent a major unmet clinical need in facing the pathophysiological scenario (Fox et al., 2018). Regarding the patient related factors impacting on the transplantation strategy, the identification of a clear trigger for referral to a HSCT center still represent a clinical challenge as well as the high frequency of comorbidities, such as severe infections and highly refractory autoimmune conditions (Castagnoli et al., 2019; Notarangelo, 2009). Some patients have a very clear indications for transplant which is malignancies or life-threatening infections or hemophagocytic lymphohistiocytosis (HLH) (Lehmberg et al., 2019). Progressive PID-related complications failing to respond to alternative therapies which will lead to irreversible organ injury also represent a HSCT indication (Carreras et al., 2019). Ongoing investigations are aiming to identify which patients with PID may benefit from HSCT (Morris, 2020). Specifically, young patients with low-grade comorbidities score, good lung and liver functions and HLH or malignancies that are in remission at the time of referral are likely to benefit and are considered at lower risk at the time of the HSCT. Moreover, the knowledge of the underlying genetic defect and phenotype make the HSCT decision easier (Dimitrova et al., 2020). Remarkably, the clinical outcome in carefully selected patients is excellent (Morris, 2020). A multicenter EBMT study confirmed the data generated by Morris et al. showing an outcome advantage in the peculiar clinical scenario of systemic granulomatous disease (Chiesa et al., 2020), demonstrating an excellent OS in the adult group, including 77 patients over the age of 18. Finally, the assessment of PID the confirmation of the functional immune deficiency should be confirmed and assessing and understanding the underlying disease is key while documenting the indication for HSCT, looking for evidence for effectiveness of allo-HSCT along with evidence for predicted poor prognosis with conservative management. Appropriate donor and patient fitness are also of paramount importance. Indeed HSCT in CVID in a retrospective multicenter study with transplant occurred between 3 and 26 years after the onset of the first symptom identified a 50% of mortality (Wehr et al., 2015), despite retrospective data warrants statistically powered trials to properly answer the unmet clinical questions. Moreover alternative novel therapies should always be taken into consideration such as targeted drugs or gene therapy and gene-editing. Of note, genetic engineering was unrevealed as a novel frontiers for deficient PIDs management, because the vast majority of inborn error of immunity are amenable in theory to correction with cellular therapy or gene editing (Picard et al., 2018). The general goal of cellular therapy is to replace the long-term HSC, while proceeding with conditioning aiming to eliminating HSC and progenitors and engrafting donor long term-HSC (LT-HSC). All of the progeny would be donor-derived. Nonetheless, donor availability, graft versus host disease (GVHD) and long-term effect represent limitations of allogeneic transplant. Moreover, since PIDs differ from malignant condition being able to be managed with medical therapy, a careful balance is necessary between the acute and chronic toxicities that after allo-HSCT might become more morbid than the disease itself (Bakhtiar et al., 2019). Lower conditioning intensity regimens are better tolerated but predispose to mixed chimerism. This holds different consequences depending on the given underlying condition. Severe combined immunodeficiency (SCID) has many genetic causes. Patients with SCID have a profound absence of T cells. X-linked SCID (SCID-X1) was the first disease to be treated with HSCT (Gatti et al., 1968). Considering the different genetic subtype of SCID, it should be considered that although B cells are still present in B+ SCID the cytokine, CD3 and other receptors defects imply a lack of CD4 T cell help, thus impacting on the B cell function (Fischer, 2000). Conversely, B cell absent SCID is characterized by recombination defects and metabolic defects that physiologically impact on immune dysfunction. The lack of CD4 T cells in SCID allows the special condition of HCT effectiveness without conditioning, since the patient has no need of immunosuppression and myeloablation to engraft T cells. Thus, if the patient has a matched sibling donor the bone marrow, peripheral blood or umbilical cord blood can simply be infused and greater than 90% of the cases are developing T cells, being rescued from opportunistic infection. Most of patients supports a lack of matched sibling donors, therefore, another strategy is to use an aplodidentical parents, removing in some ways the T cells that otherwise would cause lethal GVHD, being anyway able to obtain a successful engraftment (Pai, 2019). The reason why this unconditioned engraftment can be successful is because of the unique role of the thymus in the T-cell development and the lack of the recipient T-cell leads to a strong advantage for the donor-derived T-cells. Unlike the other lineages, T-cells mature in the thymus when bone marrow-derived HSC or progenitors enter the thymus and are induced to develop into T-cells. In the patient with SCID where there are no progenitors capable of developing into T-cells those donor-derived HSC can engraft in the thymus and give rise to donor-derived T-cells (Pai, 2019). Since nothing needs to be done to eliminate the HSC or the other progenitors all the other cells will remain of recipient origin. Chemotherapy might affect donor cell engraftment and immune reconstitution in different types of SCID, having consequences in incomplete immune reconstitution. In patients with B cells absent (B- SCID), transplant without conditioning might restore T cells but without chemotherapy the recipient HSC remain untouched and therefore the patient will still lack B cells and still lack Ig production. In the B+ SCID T cells are restored successfully the majority of the time and in theory those T cells should be able to give recipients T cell help and induce antibody production. However, IL2RG/JAK3 deficient B cells fail to function despite T cell help due to lack of IL-21 response, failing to produce humoral response after conditioning transplant because those recipients mutant B-cells remain unresponsive to IL-21 and do not function despite the provision of T cell help (Miggelbrink et al., 2018). Conditioning is needed for some types of SCID to

improve T cell number and B cell function (Pai et al., 2014, pp. 2000–2009), replacing HSC with donor HSC (Dvorak et al., 2014), which not only leads to T-cell development, but also to the development of donor-derived B cells (Haddad et al., 2018; Heimall et al., 2017). Furthermore, conditioning appears to improve T cell output by providing continuous seeding of thymus with donor-derived cells and otherwise, without conditioning the limited inoculum that engrafts in the thymus would exhaust over time.

WAS and IPEX represent different clinical scenario in which there are T cells, but donor-derived T cells or subsets of T cells in the subset of IPEX have a strong selective advantage, which is consequences for the outcomes having the states of mixed-chimerism. In details Wiskott-Aldrich syndrome, being characterized by thrombocytopenia, eczema, infections, autoimmunity and malignancy represents an X-linked disease caused by defects in WAS gene with defects in cytoskeletal function, with abnormal T cell survival, abnormal T, B, monocyte migration and small defective platelets (Moratto et al., 2011; Pai and Notarangelo, 2010; Puck and Candotti, 2006). Myeloablative conditioning is generally used for WAS syndrome, gaining an excellent survival, matching the goal of HSCT of correcting the immunodeficiency and correct the platelet count (Moratto et al., 2011). When high level donor chimerism is achieved both the lymphocyte compartment and the platelet compartment are corrected. However in the state of mixed-chimerism the lymphocyte compartment is still corrected because T-cells and to some extent B cells which express WAS protein have a survival advantage of recipient WAS negative cells and looking at the degree of donor chimerism the patients and their T cells have an high tendency of donor-chimerism; conversely in B cells and myeloid cells there are less than 50% of donor-derived cells. Infact, mixed chimerism may result in persistent thrombocytopenia and myeloid cells are more prone to mixed chimerism than T and B cells. In the donor cells there is a lack of selective advantage that may lead to a failure of platelets count recovery. A correlation exists between patients with less than 30% of donor chimerism in myeloid cells and platelet count below 50,000/mcL (Moratto et al., 2011).

In the X-linked immune dysregulation-polyendocrinopathy-enteropathy—IPEX a defect in FOXP3 gene affecting a critical transcription factor results in absence of regulatory T cells (Treg) or lack of Treg function. Thus an inability to control effector T cells and the development of autoreactive B cells, produce autoantibodies leading to dermatitis, enteropathy, autoimmune diabetes and other severe autoimmune manifestations (Seidel et al., 2009). Because of a lack of Treg a mixed chimerism after transplant at a HSC level, the conventional T cells and B cells may be mixed, but the Treg also are derived from the thymus and in the patient they are largely donor due to a selective advantage. In turn those Tregs should become capable of controlling in a dominant fashion both the normal donor T cells and the recipient T cells. If the donor-derived Tregs have a selective advantage reduced intensive regimen is putatively as good as myelo-ablative and the mixed chimerism is supposed to be as good as full donor chimerism (Seidel et al., 2009). Retrospective studied on 96 IPEX patients showed no significant differences between reduced-intensity regimen compared to the myeloablative one being mixed chimerism apparently sufficient (Barzaghi et al., 2018). Looking at organ involvement by autoimmunity prior to transplant Barzaghi et al. also found that patients with autoimmunity with organ damage that was poorly controlled before the transplant had a substantial worse survival. This data did not differ in patients who received reduced-intensity conditioning regimen and those patients who were older or younger at the time of transplant (Barzaghi et al., 2018). Therefore, the outcomes of HSCT for IPEX are likely to be better with disease control and early intervention before organ damage occurred.

In diseases in which the T-cells are dysregulated intrinsically and can potentially persist after HSCT because it is not expected that donor T cells can have a selective advantage. The poor survival for CVID treated with HSCT due to early mortality for an underlying infection (Wehr et al., 2015). Slow immune reconstitution is likely the reason why those patients experienced an unfavorable prognosis. After HSCT the donor graft contains not only HSC. And progenitors that engraft in the marrow, but also a limited amount of mature T cells from the donor that are essentially adoptively transferred to the patient. Early post-HSCT the donor HSC will start to seed the thymus but very little new T cells generation and the T cells that are circulating remain to the donor infused-cells that may expand in the neutropenic environment but remain very low in number and limited in specificity. Therefore, prolonged T lymphopenia prompts a high risk of viral and other infection. In 4–6 months new T cells derived from donor HSC emerge from the thymus (Castagnoli et al., 2019). Haploinsufficiency of CTLA4 gene, being characterized by variable penetrance, is characterized by dishinhibited effector T cells, due to reduced inhibitory CTLA4 expression and also, the Treg are poorly functional, thus not only those Treg are not able to control the T cells but fail to regulate the APC which in turn leads to further inactivation of appropriate activation of effector T cells. Thus, the goal of HSCT is to replace the Tregs with functional cells and eliminate the dysfunctional CTLA4 deficient effector T cells. In the retrospective review from Schwab et al. of 133 CTLA4 haploinsufficient patients, 12 received HSCT, all having unrelated donors, receiving either standard or reduced intensity conditioning regimen three died and one subject passed succumbed due to diabetic ketoacidosis which highlights the fact that even with the correction of the immune system organ damage that was already sustained will not be corrected. Interestingly, almost all patients with high-level chimerism had improvement or remission of disease. Remarkably, one patient with 60% T cell chimerism and 100% all other lineages, had CMV reactivation, ARDS, chronic steroid treatment (Schwab et al., 2018). Thus, a failure to eliminate recipient T cells and mixed chimerism in T cells is deleterious for the outcome. Therefore, in order to prevent mixed T cell chimerism from occurring warrants an understanding of two main mechanisms. These patients experience a full engraftment of HSC, however, some recipient T cells fail to be completely eliminated and those T cells persist. Secondly, the patient can develop mixed chimerism at HSC level in which case not only might there be some rebound of recipient T cells in the periphery that escaped conditioning, but also, it can be an output of new T cells some of which are donor-derived and some of which remain CTLA4 haploinsufficient. Therefore, in order to succeed with conditioning regimen recipient T cells that are intrinsically overactive must be shrunk down and HSC mixed chimerism should be avoided. Finally, in APDS the graft failure and survival represent a major challenge (Nademi et al., 2017), with older age as a risk factor for poor survival as well (Leiding and Forbes, 2019).

Given the above mentioned challenges, ex vivo gene therapy is a particularly attractive option, particularly for blood disorder (Moreno-González and Zarain-Herzberg, 2013). The concept is that by introducing a gene into the LT-HSC pool will sustain the expression of the gene and all the progeny of that LT-HSC will carry the gene. Thus, gene therapy is an alternative to allo-HSCT, since, instead of identifying a donor stem cells are harvested either from the bone marrow or peripheral/umbilical cord blood, the HSC can be technologically enriched by using the antigen CD34 and a vector subtypes (i.e., a gamma retrovirus - γ RV) allow the introduction of a gene copy. Next, is possible to cryopreserve the stem cells, insuring that they have sufficiency of gene transfer and allow the patient to be prepared to appropriate conditioning and receive an auto-HSCT rather than allo-HSCT. Obviously, being the patient its own donor, no GVHD is reported and as long as the transduction of a sufficient number of HSC is obtained the vector integrates efficiently into the DNA of the cell, and passes the gene to all progeny. SCID-X1 and ADA SCID were the first to be treated with ex vivo gene therapy (Aiuti et al., 2002; Cavazzana-Calvo et al., 2000). Encouraging trials are ongoing in ADA-SCID, X-linked SCID, Artemis SCID, Wiskott-Aldrich and X-linked CGD (De Ravin et al., 2016; Morgan et al., 2017).

Introduction

Secondary immunodeficiencies (SID) represent the immune disorders that are acquired later in life, as opposed to those that result from an inborn (genetic) defect in the immune system (Fudenberg et al., 1970). Any acquired disease or exposure which increases susceptibility to infection can be considered a secondary immunodeficiency in the largest sense. For example, disorders that disrupt skin and mucosal barriers, such as surgery, trauma, burns, or malnutrition increase the host's susceptibility to infection (Chinen and Shearer, 2010). Similarly, the introduction of medical devices such as indwelling catheters and prostheses bypasses the first line of defense against infection. However, these conditions are beyond the scope of this article.

The immune system can be divided into the innate and adaptive arms. The innate immune system is primed to seek and destroy invading microorganisms within minutes. Phagocytes, such as neutrophils, monocytes, macrophages, and dendritic cells (DCs), recognize evolutionarily conserved pathogen associated molecular patterns (PAMPs) via pattern-recognition receptors (PRR; e.g., Toll-like receptors), which allow them to ingest and kill bacteria and fungi. In recent years, there has been a greater appreciation for non-hematopoietic cells, such as muco-cutaneous epithelial cells and neuronal cells, also playing relevant roles in human innate immunity, using similar PRR processes (Casanova and Abel, 2007). In addition to microbial killing, phagocytes act as antigen-presenting cells and produce cytokines, activating the adaptive arm of the immune system to provide antigen-specific and memory responses against pathogens (Turvey and Broide, 2010). Natural killer (NK) cells and natural killer T (NKT) cells are lymphocytes that are also considered members of the innate immune system due to their ability to kill virally infected cells

independently of major histocompatibility complex (MHC) class I-mediated antigen recognition (Orange, 2013). Complement further provides a humoral component to the innate immune system through the lysis of bacterial membranes and opsonization (Hajishengallis et al., 2017).

The adaptive arm of the immune system temporally follows the innate arm in the response to microorganisms. Whereas the innate arm recognizes fixed microbial motifs, the adaptive arm can recognize an infinite number of antigens (epitopes) due to genetic recombination of their immunologic receptors during their development. It can also distinguish between self- and non-self-antigens (Bonilla and Oettgen, 2010). B cells are responsible for the humoral component of the adaptive immune system through the production of antibodies. Recognition of a new antigen leads to B cell proliferation, isotype switching from immunoglobulin M (IgM) to immunoglobulins G (IgG), A (IgA), or E (IgE), affinity and avidity maturation, and differentiation into long-lasting plasma cells that continue to produce mature antibody to protect from further exposure. Antibodies both neutralize virulence factors and act as opsonins for the innate arm (Murphy, 2012).

T cells play a key role in the cellular component of the adaptive immune system (i.e., cell-mediated immunity, CMI). Following maturation in the thymus by both positive and negative selection, egressed naïve T cells require specific signals to become activated ("two-signal" hypothesis): Firstly, there is cognate interaction between T cell receptors (TCRs) binding to peptide-loaded, cell surface-expressed human leukocyte antigen (HLA, or major histocompatibility complex, MHC) (Azuma, 2019). Self-antigens should lead to tolerance. In the presence of non-self-antigens, co-stimulation (second signal) leads to clonal expansion and an effector response. CD8⁺ T cells (or cytotoxic T lymphocytes, CTL) primarily bind to MHC class I (HLA-A, B, and C) presented by all nucleated cells and destroy cells expressing non-self-antigens by releasing the contents of their cytotoxic granules. CD4⁺ (T helper) cells, on the other hand, bind to MHC class II (HLA-DP, -DQ, or -DR) presented by professional antigen presenting cells, such as phagocytes and B cells, and strengthen effector responses to viruses and intracellular pathogens through the display of surface ligands and production of cytokines, as well as stimulate B cells toward antibody maturation (Bonilla and Oettgen, 2010).

Secondary immunodeficiencies (SID) can affect the innate, humoral, or CMI components of the immune system, alone or in combination. This can be due to an absolute deficiency in the component of the immune system, such as neutropenia, hypogammaglobulinemia, or lymphopenia, or a functional deficiency of an apparently quantitatively normal component. Both quantitative and qualitative defects can occur concomitantly or serially. These deficiencies can arise due to disease states, immunosuppressive treatments, or a combination. This is especially true in the case of lymphoid malignancies which result in complex absolute and functional deficiencies of multiple components due to both the underlying disease and its treatment (Friman et al., 2016). It is critical for the physician seeking to treat patients with secondary immunodeficiencies and their resulting infections to understand this complex interplay between the components of the immune system, disease states, and immunosuppressive treatments.

Phagocyte deficiencies

Neutropenia is one of the most common SID encountered by physicians, typically due to cytoreductive therapies (e.g., in hematological malignancies), with febrile neutropenia constituting a medical emergency. Neutropenia is defined as an absolute neutrophil count (ANC) of less than 1500 cells μL^{-1} , with an ANC of less than 500 cells μL^{-1} being considered severe neutropenia (World Health Organization, 1979). The risk of infection is directly correlated with both the severity and duration of neutropenia, with prolonged neutropenia generally defined as lasting longer than 7–14 days (Sipsas et al., 2005; Gerson et al., 1984; Abers et al., 2016; Zimmer and Freifeld, 2019; Taplitz et al., 2018). Neutropenic patients are at particular risk of life-threatening sepsis due to both gram-positive and gram-negative bacteria (including *Pseudomonas aeruginosa*), as well as fungemia due to yeast. Despite a thorough diagnostic evaluation, a clear infectious focus is not found in most episodes of febrile neutropenia, with only 50% presenting with clinically-documented infection (objective and detectable signs of infection with a lack of microbiological documentation) and as little as 12% patients having a microbiologically-documented infection (Lehrnbecher et al., 2017; Hakim et al., 2009; Immunocompromised Host Society, 1990). However skin and soft tissue infections (SSIs), viral and bacterial pneumonia, central line associated bloodstream infections (CLABSIs), and bacterial urinary tract infections can serve as foci of dissemination. It is key for clinicians to recognize that typical purulent manifestations of these infections may not manifest themselves until neutrophil recovery and a high index of suspicion must be maintained when evaluating the neutropenic patient.

In addition to bacterial sepsis, prolonged neutropenia is an important risk factor for fungal infection by both yeasts and molds. Mucosal infections with *Candida* species, including oropharyngeal candidiasis and esophagitis, occur in up to 40% of patients receiving cancer treatment (Lalla et al., 2010). Invasive *Candida* infections can present acutely, as is the case with candidemia, or chronically as is the case with disseminated ("hepatosplenic") candidiasis. Candidemia can further result in endophthalmitis, osteomyelitis, endocarditis, or central nervous system infection through hematogenous spread (Sims et al., 2005). Disseminated trichosporonosis can rarely mimic disseminated hepatosplenic candidiasis in the setting of prolonged neutropenia (Marty et al., 2003).

Prolonged neutropenia is the most important risk factor for invasive infection with molds, particularly invasive pulmonary aspergillosis (IPA) and disseminated aspergillosis (Gerson et al., 1984). *Scedosporium* spp. and *Lomentospora* spp. present similarly to *Aspergillus* spp., however these agents are often multidrug resistant and are particularly difficult to treat. Disseminated fusariosis and invasive mucormycosis, especially rhinocerebral and pulmonary disease, are widely feared due to the extensive tissue destruction they cause, the paucity of effective antifungal therapies against them, and their lethality (Lamoth and Kontoyiannis, 2019). Fever greater than 38 degrees Celsius for more than 48–72 h despite appropriate antibiotic therapy; new pulmonary nodules or infiltrates;

facial, sinus, or ocular pain; or new or rapidly progressive painful and nodular, necrotic, or ulcerative skin lesions in a neutropenic patient should prompt a thorough investigation for invasive mold infection and strong consideration of empiric antimold treatment.

Compared to neutropenia, secondary monocytopenia is rarely encountered by clinicians and can be easily overlooked. Both genetic and acquired monocyte disorders predispose to invasive pulmonary and disseminated infections with non-tuberculous mycobacteria, *Nocardia* spp., *Aspergillus* spp., *Cryptococcus neoformans*, and *Histoplasma capsulatum* (Punatar et al., 2012; Vinh et al., 2010).

Causes of secondary phagocyte deficiencies

Due to medical conditions

Both functional and absolute neutropenia can occur due to decreased or dysfunctional production of neutrophils in the bone marrow, organ sequestration, or peripheral destruction. Dysmyelopoiesis occurs in the setting of myeloid malignancies, particularly acute myelogenous leukemia (AML), myelodysplastic syndrome (MDS), and myeloproliferative neoplasms (MPNs). Neutrophils produced from the abnormal clone can be both reduced in number and dysfunctional, such that patients with apparently normal neutrophil counts can still experience severe and recurrent invasive bacterial and fungal infections. Prolonged and severe absolute neutropenia is also observed in acquired bone marrow failure syndromes, such as idiopathic aplastic anemia, toxin-mediated myelosuppression, micronutrient deficiencies, and bone marrow infiltration by neoplasia and infections (Peslak et al., 2017). Splenomegaly is a frequent cause of leukocyte sequestration typically causing a mild-to-moderate absolute neutropenia. This becomes more important in patients with advanced cirrhosis who experience multifactorial phagocyte dysfunction associated with reduced function due to accumulated toxins, reduced numbers of sinusoidal macrophages, and leukocyte sequestration due to secondary hypersplenism (Irvine et al., 2019). Immune neutropenia, resulting in autoimmune peripheral destruction of neutrophils, can occur on its own or accompanying other autoimmune phenomena, especially systemic lupus erythematosus (SLE) (Meyer et al., 2020).

Pulmonary alveolar proteinosis (PAP) is one of the most well described acquired monocyte disorders. PAP is characterized by impaired clearance of cholesterol from the alveoli leading to dysfunctional surfactant as well as a susceptibility to infection due to macrophage dysfunction. Most cases are caused by neutralizing autoantibodies to granulocyte-macrophage colony stimulating factor (GM-CSF) (Trapnell et al., 2019). Opportunistic infections occur in more than half of patients diagnosed with PAP, with 40% presenting with an infection as the first manifestation of the disease (Punatar et al., 2012).

Hairy cell leukemia (HCL), a B-cell monoclonal disorder, induces both severe neutropenia and monocytopenia with a marked susceptibility to infection in up to 60% of untreated patients (Kraut, 2011; Grever et al., 2017). Patients can present with severe infections typically associated with neutropenia (e.g. *P. aeruginosa* sepsis and invasive fungal infections) and infections associated with monocytopenia (notably disseminated non-tuberculous mycobacterial infections) (Stewart and Bodey, 1981). While the risk of these infections decreases with therapy, new infectious risks are introduced due to profound iatrogenic T cell immunosuppression related to chemotherapy (see later in chapter) (Kraut, 2011).

Iatrogenic causes

Myelosuppressive chemotherapy is the most common iatrogenic cause of absolute neutropenia encountered in clinical practice. However, diverse non-chemotherapy medications can cause predictable or idiosyncratic absolute neutropenia due to either direct myelosuppression or immune-mediated causes (see Table 1) (Curtis, 2017; Clément et al., 2018). High-dose radiation, particularly whole-body treatments or treatments focused on the pelvis can also be myelosuppressive.

Glucocorticoids are broad spectrum immunosuppressant medications that act in part through inhibition of both neutrophil and monocyte activity. Multiple phagocytic functions are impaired by glucocorticoids, including chemotaxis, phagocytosis, and the oxidative burst, increasing susceptibility to both bacterial and invasive fungal infections, particularly invasive pulmonary mold infections (Llewellyn-Jones et al., 1994; Petroni et al., 1988). Phagocyte dysfunction and infectious risk increase with both the dose and duration of therapy and are additive to existing phagocyte disorders. The immunosuppressive effects of glucocorticoids on adaptive immunity are discussed later in the chapter.

Treatment of secondary phagocyte deficiencies

The goals of treatment of neutropenia are threefold: (1) to correct the functional or absolute neutropenia; (2) primary prevention of opportunistic infections through prophylactic antibacterial and antifungal treatment; and (3) early diagnosis and management of opportunistic infections. The acute management of febrile neutropenia is beyond the scope of this article.

Correction of neutropenia

Treatment of the underlying disease or dose reduction, delay, or removal of the offending drug are the mainstays of treatment for secondary neutropenia. However, this is not always possible and neutrophil recovery can take time, leaving the patient vulnerable to life-threatening infection. Thus, growth factor support is often used prophylactically, during myelosuppressive chemotherapy, or as treatment of severe neutropenia due to the various causes listed above.

Table 1 Classes of drugs associated with absolute neutropenia.

Type of drug	Drug class	Examples of drugs
Antibacterial	β -lactams	Benzylpenicillin
		Amoxicillin
		Piperacillin-tazobactam
		Ceftriaxone
		Cefotaxime
		Cefepime
		Meropenem
		Vancomycin
		Sulfadiazine
		Sulfamethoxazole-trimethoprim
	Glycopeptides	Chloramphenicol
	Sulfonamides	Clindamycin
	Chloramphenicol	Tobramycin
	Lincosamides	Ciprofloxacin
Antiviral	Aminoglycosides	Linezolid
	Quinolones	Tedizolid
Antihelminth	Oxazolidinones	Metronidazole
	Nitroimidazole	Ganciclovir
Antithyroid	Thionamides	Valganciclovir
		Levamisole
Antidiabetic	Thiourea	Carbimazole
		Methimazole
Antipsychotic	Sulfonylurea	Propylthiouracil
		Glyburide
Antiepileptic	Atypical antipsychotics	Clozapine
		Quetiapine
Immunomodulatory	Iminostilbene derivatives	Carbamazepine
		Phenytoin
Cardiovascular	Hydantoin	Ibuprofen
		Tacrolimus
	NSAIDs	Mycophenolate mofetil
		Everolimus
	Calcineurin inhibitors	Clopidogrel
		Ticlopidine
	IMP dehydrogenase inhibitors	Disopyramide
		Procainamide
	mTOR inhibitors	Quinidine
		Captopril
	P2Y ₁₂ inhibitor	Spironolactone
		Methyldopa
	Antiarrhythmic	
	ACE inhibitor	
	Diuretic	
	Alpha-2 agonist	

Recombinant granulocyte colony stimulating factor (G-CSF) and granulocyte-macrophage colony stimulating factor (GM-CSF) can be used to stimulate neutrophil and, in the case of GM-CSF, monocyte production and mobilization from the bone marrow. G-CSF is more commonly used to treat acquired neutropenia as GM-CSF is more pro-inflammatory, unless an increase in macrophage function is also desired in which case GM-CSF is preferred (Mehta et al., 2015). As per the American Society of Clinical Oncologists' (ASCO) 2015 Clinical Practice Guideline, G-CSF treatment is recommended as primary prevention of infection in patients receiving high-risk chemotherapy regimens (greater than 20% risk of febrile neutropenia) and secondary prevention for patients who have experienced previous episodes of febrile neutropenia during chemotherapy. It may also be used to prevent infection in patients with idiopathic or immune-mediated neutropenia, or neutropenia due to aplastic anemia or non-chemotherapy myelosuppressive medications (Dale and Bolyard, 2017). G-CSF treatment is generally not indicated for treatment of an active episode of febrile neutropenia as it neither reduces mortality nor duration of hospitalization (Mehta et al., 2015). In cases of invasive mold infections, however, G-CSF may be used to accelerate neutrophil recovery which is critical for the control of the infection and may be lifesaving. This approach is supported by experimental data from animal models of *Aspergillus* infection (Patera et al., 2004; Sionov et al., 2005).

G-CSF and GM-CSF can be given either intravenously or subcutaneously, however the subcutaneous route is preferred due to ease of administration and, in the case of G-CSF, more rapid neutrophil recovery (Paul et al., 2014). Inhaled GM-CSF is also used as treatment of autoimmune PAP (Trapnell et al., 2020). Pegylated forms of G-CSF which require less frequent dosing are marketed along with traditional recombinant G-CSF (see Table 2). Both agents can cause fever and bone pain, however this is more common

Table 2 Formulations and dosing of recombinant G-CSF and GM-CSF.

	Formulation	Recommended Dose	Dosing Frequency
G-CSF	Filgrastim	5 $\mu\text{g kg}^{-1}$	Daily (duration depending on chemotherapy regimen)
	PEG-filgrastim	6 mg	Once 24 h after receiving each cycle of chemotherapy
GM-CSF	Sargramostim	250 $\mu\text{g m}^{2(-1)}$	Daily
	Molgramostin	5–10 $\mu\text{g m}^{2(-1)}$ injection or 300 μg inhalation	Daily

with GM-CSF treatment. These can be treated symptomatically with antipyretics or antihistamines, respectively. GM-CSF has also been reported to be associated with pleural and pericardial effusions. Growth factors must be used cautiously in patients with MDS or MPNs as they can theoretically predispose to transformation to AML (Mehta et al., 2015). Long-term treatment with G-CSF in children has been associated with low bone mineral density, however this has not been demonstrated in adults and causality has not been established (Dale et al., 2003).

Donor granulocyte transfusion was historically used to prevent and treat opportunistic infections in neutropenic patients before the advent of recombinant growth factors. It remains an option in patients who do not or cannot respond to growth factor support. Unfortunately, this approach requires timely access to a human leukocyte antigen (HLA)-matched donor and infusion of the cells within 24 h due to their short shelf life. Infused allogeneic granulocytes can also result in alloimmunization and transfusion related acute lung injury (TRALI) (Cugno et al., 2015). Furthermore, while prophylactic granulocyte transfusion does modestly reduce invasive bacterial and fungal infections when given in a sufficient dose, no clear all-cause or infection-related mortality benefit has been demonstrated in randomized clinical trials performed to date (Estcourt et al., 2015). As well, the optimal target level of neutrophil count to achieve is undefined. Thus, due to impracticality, toxicity, and questionable clinical efficacy, this approach is only used to treat life threatening or refractory infections in neutropenic patients, especially invasive mold infections (Patterson et al., 2016; Dignani et al., 1997; Mousset et al., 2005; Kadri et al., 2015).

Prophylactic antimicrobial therapy

Antibacterial prophylaxis

Quinolone prophylaxis is recommended by ASCO and the Infectious Diseases Society of America (IDSA) for patients receiving chemotherapy who are expected to experience profound and prolonged neutropenia refractory to growth factor support (Taplitz et al., 2018). This applies particularly to patients undergoing induction and consolidation therapy for AML as well as HSCT with a standard conditioning regimen. Therapy is recommended for the duration of severe neutropenia. This recommendation is based on over 100 trials that have demonstrated a mortality benefit for quinolone prophylaxis in this population. In the most recent (2012) Cochrane systematic review and meta-analysis of available randomized controlled trials, antibiotic prophylaxis reduced all-cause mortality by 34% and infection-related mortality by 39%, with a number needed to treat to prevent one death of 55 (Gafer-Gvili et al., 2012). However, this enthusiasm is tempered by concerns about rising quinolone resistance rates worldwide, selection for quinolone-resistant clones, effects on the gut microbiota, and the association between quinolone therapy and *Clostridioides difficile* infection (CDI) (Bow, 2011).

Antifungal prophylaxis

ASCO and the IDSA equally recommend antifungal prophylaxis for the duration of neutropenia in patients receiving chemotherapy regimens expected to cause profound neutropenia. Again, this applies essentially to patients receiving induction for AML or HSCT (Taplitz et al., 2018). However, not all such patients require prophylaxis with a mold-active agent. In patients undergoing chemotherapy for AML or MDS, prophylaxis with the antimold agent posaconazole reduces invasive fungal infection and mortality compared to fluconazole or itraconazole and is the standard-of-care (Cornely et al., 2007). In patients with severe graft-versus-host disease (GVHD), fluconazole and posaconazole were equivalent for the prevention of invasive fungal infection and mortality, however posaconazole demonstrated superiority for the prevention of invasive aspergillosis and fungal infection-specific mortality and is the recommended antifungal prophylaxis in this population (Ullmann et al., 2007). In HSCT recipients without GVHD, on the other hand, mold-active prophylaxis does not provide a survival advantage and prophylaxis with fluconazole alone is recommended until neutrophil recovery. Voriconazole and isavuconazole may be used as alternatives to posaconazole when antimold prophylaxis is indicated (Barreto et al., 2013; Bose et al., 2021). Echinocandins have been found to be superior to fluconazole for antifungal prophylaxis in patients undergoing AML induction or consolidation or HSCT and may be used as an alternative to triazoles for invasive yeast infection prophylaxis in these populations; however, they are much less active against molds than broad-spectrum azoles (Fisher et al., 2019; Van Burik et al., 2004). Inhaled amphotericin B deoxycholate and liposomal amphotericin B are also alternatives for antimold prophylaxis, however they are rarely used given the existence of more practical alternatives (Duckwall et al., 2019).

B cell deficiencies

B cell disorders can result in immunoglobulins which are quantitatively decreased in number (hypogammaglobulinemia; HGG) and/or qualitatively impaired in their ability to adapt to new antigens (dysgammaglobulinemia). Deficiencies of the IgG class are the most clinically significant and actionable. Quantitatively, IgG may even appear misleadingly elevated, yet be dysfunctional, as seen in some plasma cell dyscrasias (e.g., multiple myeloma) or B cell lymphoproliferative disorders (e.g., chronic lymphocytic leukemia). IgM and IgA can be similarly abnormal. Thus, quantitative immunoglobulin assays only tell part of the story.

Acquired B cell deficiencies mostly manifest as recurrent bacterial infections: these infections may even be the first symptom of the underlying disorder. These infections are primarily with encapsulated bacteria including *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis* and manifest mostly as recurrent sinopulmonary infections and otitis media, but serious infections such as empyema, bacteremia, and meningitis also occur (Casulo et al., 2013; Picard et al., 2003). Over time, these recurrent pulmonary infections can lead to bronchiectasis and pneumatocoles (Ruffner et al., 2017; Brent et al., 2016). A predisposition to gastrointestinal infections with *Campylobacter* spp., *Salmonella* spp., and *Giardia lamblia* has also been noted in patients with genetic B cell deficiencies; whether this applies to patients with SID is unknown (Hagiya et al., 2018; Barmettler et al., 2017; Oksenhendler et al., 2008). The severe congenital B cell deficiency X-linked agammaglobulinemia is also associated with invasive and refractory enteroviral infections; whether this is true in acquired B cell disorders is also unclear (Galama, 1997). Finally, during the recent COVID-19 pandemic, patients treated with B cell depleting agents were found to have prolonged viral shedding and symptoms which abated with anti-SARS-CoV-2 antibody treatment (Hueso et al., 2020). Whether this applies to other respiratory viruses is unknown and will be an area for future study.

The evaluation of patients suspected of harboring a secondary B cell immunodeficiency begins with a clinical history to elicit recurrent infections suggestive of this disorder. Investigations should include quantitative IgG, IgA, and IgM levels, as well as vaccination with a conjugated protein vaccine and a polysaccharidic vaccine to evaluate serologic responses, which serves as a functional assay of B cell activity. Ancillary investigations include a complete blood count, serum protein electrophoresis, serum free light chains, and chest imaging to detect common causes of secondary B cell disorders (e.g., thymoma, see below) and pulmonary complications (e.g., bronchiectasis).

Causes of secondary B cell disorders

Due to medical conditions

The medical conditions most associated with B cell disorders are clonal B cell malignancies. This is best described in chronic lymphocytic leukemia (CLL), in which a dysfunctional clone dominates the B cell population to the detriment of functional B cells. CLL is associated with serious or recurrent bacterial infections in 55% of patients not receiving immunoglobulin prophylaxis (Cooperative Group for the Study of Immunoglobulin in Chronic Lymphocytic Leukemia, 1988). The incidence of recurrent and serious infections is associated with HGG, deficiency of IgG subclasses, and deficiency of pneumococcal specific antibodies, supporting the notion that both HGG and dysgammaglobulinemia explain these patients' susceptibility to infection (Griffiths et al., 1992; Freeman et al., 2013). Other B cell lymphomas may also be associated with susceptibility to infection through similar mechanisms, but the frequency is not as well defined as for CLL.

Similarly, the plasma cell dyscrasias represent clonal proliferation of plasma cells (memory cells responsible for prolonged production of mature antibody) which produce an abnormal clonal antibody peak that replaces normal antibody production and results in marked dysgammaglobulinemia. Plasma cell dyscrasias associated with increased susceptibility to infection include plasma cell malignancies such as multiple myeloma (MM) or plasma cell leukemia and mature B-cell lymphomas which produce abnormal antibody, most notably Waldenström's macroglobulinemia (WM) in a patient with lymphoplasmacytic lymphoma (Swerdlow et al., 2016). In a case series of over 9000 multiple myeloma patients, the risk of bacterial infection was found to be increased seven-fold over the general population, and the risk of viral infection was increased 10-fold. Infection was the cause of death in 22% of patients who died during follow-up (Blimark et al., 2015). This is thought to extend to patients with WM as well.

Good's syndrome is marked by HGG, as a manifestation of a combined (B- and T- cell) immunodeficiency associated with thymoma. Despite thymectomy, HGG and sinopulmonary infections (as well as the T cell deficiency with opportunistic infections) can persist. Many cases require immunoglobulin replacement therapy (IGRT) to address the HGG. The mechanism(s) underlying the severe B and T cell lymphopenia in these patients has yet to be determined (Zaman et al., 2019).

In addition to defective antibody production, excessive protein loss can result in HGG, as seen notably in protein-losing enteropathy and nephrotic syndrome (Ye et al., 2019; Ameratunga et al., 2015). Nephrotic syndrome in children predisposes to pneumonia, bacteremia, spontaneous bacterial peritonitis (SBP) and UTI, with the most common organism being *Streptococcus pneumoniae* (Carpenter et al., 2019; Malaker et al., 2019). Active nephrotic range proteinuria and hypoalbuminemia less than 15 g L⁻¹ are most associated with the risk of infection (Lebel et al., 2020; Kumar et al., 2019). There is less clinical evidence of an association between gastrointestinal spillage of antibody and infection, however it is plausible that such HGG predisposes to invasive bacterial infection in a similar manner to patients with nephrotic syndrome.

Iatrogenic causes

Targeted B cell depleting agents have revolutionized the management of B cell leukemias, B cell lymphomas and multiple myeloma. They are equally approved for the treatment of rheumatoid arthritis, auto-immune hemolytic anemia, refractory immune thrombocytopenic purpura (ITP), granulomatosis with polyangiitis, and microscopic polyangiitis, but are also used off-label to treat connective tissue diseases, multiple sclerosis, pemphigus vulgaris, and diverse autoantibody-mediated diseases (Sarsour et al., 2020). These agents include monoclonal antibodies against diverse surface targets and CD20-targeted chimeric antigen receptor T (CAR T) cell therapies (see Table 3) (Patel et al., 2019). Monoclonal antibodies target B cells for destruction through antibody-dependent cytotoxicity, while CAR T cells direct cytotoxic T cells to destroy any cell displaying the target antigen.

Half of patients receiving rituximab develop HGG, which is associated with an increased risk of severe infections for 6 months after administration of the last dose (Barmettler et al., 2018). Serum immunoglobulins continue to decrease with subsequent doses of rituximab and remain persistently depressed as long as therapy continues; this effect is additive to the effect of previous or concurrent treatments, especially cyclophosphamide and systemic steroids (Tieu et al., 2021). In some patients, severe HGG can persist over 2 years after discontinuation of therapy and continue to be associated with severe infections (Levy et al., 2014). While most data exist for rituximab as it has been marketed the longest, other anti-CD20 monoclonal antibodies are likely to be associated with a similar incidence of HGG and infection. The anti-CD19 agent, blinatumomab, which targets both mature B cells and plasma cells, results in profound HGG in patients who respond to therapy, which appears to resolve on discontinuation (Zugmaier et al., 2014). Similarly, the anti-CD38 agent, daratumumab, is also associated with HGG in 60% of patients with 25% developing significant infections (Paul et al., 2019).

Ibrutinib, a Bruton's tyrosine kinase (Btk) inhibitor which has been marketed since 2015, is approved for the treatment of CLL, mantle cell lymphoma, WM, and refractory GVHD. It has been associated with serious infections in 11.4% of patients in the first year of treatment (Varughese et al., 2018). While most of these infections were bacterial, ibrutinib treatment has also been associated with an alarming incidence of invasive fungal infection, including central nervous system aspergillosis, and *Pneumocystis jiroveci* infection (Varughese et al., 2018; Lionakis et al., 2017). The mechanism(s) underlying this increased susceptibility to fungal infection is an area of active investigation. However, because CLL is not inherently associated with increased risk of these fungal infections, physicians should be vigilant about this possibility in a patient with CLL being treated with ibrutinib, and perhaps other emerging tyrosine kinase inhibitors, particularly in the first 6 months of therapy.

Hypogammaglobulinemia is being increasingly recognized post-solid organ transplantation (SOT). In a 2013 meta-analysis of 12 published studies on the topic (Florescu et al., 2013), 45% of patients were found to be hypogammaglobulinemic in the first year after transplant; of these, a third were severe ($<4 \text{ g L}^{-1}$). The prevalence of HGG depended on the organ transplanted, with the highest prevalence in lung transplant recipients (63%), followed by heart (49%), kidney (40%) and liver (15%). Similarly, 60% of intestinal transplant recipients exhibited severe HGG (Farmer et al., 2013). Severe HGG was associated with an increased incidence of respiratory, cytomegalovirus (CMV), *Aspergillus*, and other fungal infections. Importantly, it was also associated with increased mortality in the first year after SOT (Florescu et al., 2013). It has not been established whether HGG is the cause of these infections, or rather a surrogate marker of more intense immunosuppression. The causes of HGG in SOT recipients are multifactorial, including use of alemtuzumab conditioning, steroids, mycophenolate mofetil maintenance, use of B cell-depleting agents to treat antibody-mediated rejection, and, in the case of heart transplantation, removal of antibodies by cardiopulmonary bypass during surgery.

Mechanical removal of antibodies can occur through plasmapheresis, cardiopulmonary bypass (CPB), and extracorporeal membrane oxygenation (ECMO) which can result in a transient hypogammaglobulinemia. This is most noticeable in infants undergoing cardiac surgery due to their small blood volume relative to the size of the CPB circuit (Rhodes et al., 2014).

Table 3 Available B cell depleting agents.

Target	Type	Medication
Anti-CD20	Monoclonal antibody	Rituximab
		Veltuzumab
		Ocrelizumab
		Ofatumumab
		Obinutuzumab
		Ublituximab
Anti-CD22	Monoclonal antibody	Epratuzumab
Anti-CD19	Monoclonal antibody	Blinatumomab
	CAR T cell	Tisagenlecleucel
		Axicabtagene ciloleucel
CD52	Monoclonal antibody	Alemtuzumab
CD38	Monoclonal antibody	Daratumumab
		Isatuximab
BAFF	Monoclonal antibody	Belimumab

Treatment of secondary B cell disorders

Both vaccination against encapsulated organisms and pooled immunoglobulin replacement can be used to prevent invasive bacterial infections in hypogammaglobulinemic patients. The efficacy of these treatments depends on the underlying condition and whether it is being used as primary or secondary prevention.

Vaccination

Vaccines are ideally provided before the initiation of iatrogenic B cell depletion; in the case of HGG due to medical conditions, this timing is often not possible. Vaccination with a conjugated pneumococcal vaccine, followed 8 weeks later by a polysaccharidic vaccine, is recommended for patients with the conditions and treatments mentioned above. Conjugated vaccines, which induce a T and B cell response, are more immunogenic in patients with CLL than polysaccharidic vaccines, which only induce a B cell response, and thus must be included in any effective vaccination regimen (Sinisalo et al., 2001). It is also prudent to administer *Haemophilus influenzae* type B, quadrivalent meningococcal (serogroups A, C, Y, W135), and meningococcal serogroup B vaccines to patients with hematological malignancies expected to receive B cell depleting therapies and in anticipation of hematopoietic or solid organ transplant (Danziger-Isakov and Kumar, 2019). Interestingly, in nephrotic syndrome, there is a paucity of evidence to vaccinate against encapsulated organisms other than pneumococcus (Goonewardene et al., 2019). Annual influenza vaccination is generally recommended in all immunocompromised individuals as well, however patients actively receiving B cell-depleting therapy may have attenuated antibody responses (Van Assen et al., 2010; Yri et al., 2011). It should also be noted that patients with untreated CLL or those receiving active treatment had little-to-no antibody response to the BNT162b2 mRNA vaccine against COVID-19, while 75% of those who had completed treatment and were in remission had a measurable antibody response to the vaccine (Herishanu et al., 2021).

Immunoglobulin replacement

The immunoglobulin fraction can be separated from whole blood and plasma donations for adoptive transfer to patients with hypogammaglobulinemia (i.e., “passive immunization” or immunoglobulin replacement therapy, IGRT). These pooled products are derived from thousands of donors and thus contain naturally acquired and vaccine-induced specific antibodies against a variety of pathogens. IGRT may be administered intravenously (IVIG) or subcutaneously (SCIG). IVIG is typically administered as 400 mg kg⁻¹ every 3–4 weeks, while traditional SCIG preparations are administered on a total weekly dose; newer, higher concentration (20%) SCIG preparations can be administered with a 2–4-week delay between infusions. SCIG has the advantage of being self-administered (either manually or using an infusion pump), thus limiting the disruption to the patient's life from having to attend a clinic or infusion center to receive IVIG (Lachance et al., 2016).

IGRT can result in several immediate and delayed adverse events. These adverse events appear to be more common with IVIG than SCIG. Immediate reactions include flu-like symptoms, urticaria, dyshidrotic eczema, and rarely, anaphylaxis and transfusion-related acute lung injury (TRALI). Delayed events include thrombosis, headache, aseptic meningitis, posterior reversible encephalopathy syndrome (PRES), hemolysis, neutropenia, and hyponatremia. Infection risk has been significantly reduced with donor questionnaires, serological screening, and physico-chemical treatment of product during the manufacturing process; however, it remains theoretically possible to acquire bloodborne infections from any blood product (Guo et al., 2018). Also, as immunoglobulins are pooled products, IGRT can result in false positive serological assays due to passive transfer of antibody (L'Étoile-Morel et al., 2021).

Since the first trial showing a significant reduction in serious infections with IVIG therapy in CLL patients with a history of recurrent infections or HGG (Cooperative Group for the Study of Immunoglobulin in Chronic Lymphocytic Leukemia, 1988), six more trials have consistently demonstrated a decrease in infections with IGRT (Griffiths et al., 1989; Sklenar et al., 1993; Jurlander et al., 1994; Chapel et al., 1994a; Gamm et al., 1994; Boughton et al., 1995; Molica et al., 1996). A single multicenter study also showed efficacy of prophylactic IVIG to prevent bacterial infections in MM patients (Chapel et al., 1994b). More recently, SCIG administration was found to result in more sustained circulating levels of IgG, associated with more effective prevention of infection than IVIG (Visentin et al., 2018). While IGRT is clearly effective at preventing infections in patients with these malignancies, there is significant interindividual and geographic variability in the threshold at which it is prescribed. Some physicians and jurisdictions provide replacement for all hypogammaglobulinemic patients with these malignancies, while others only do so in patients who have had recurrent invasive infections. Immunologists are more likely to prescribe SCIG than non-immunologists, who are more likely to prescribe IVIG (Na et al., 2019).

The evidence of benefit for IGRT in SOT recipients with HGG in preventing infections is mixed. While it has been found to reduce mortality in heart transplant recipients, it had no effect on mortality in lung or renal transplant recipients; there was inadequate published data to reach a conclusion in other organ transplants (Bourassa-Blanchette et al., 2019a,b). The efficacy against CMV and bacterial infections was also inconclusive (Bourassa-Blanchette et al., 2019a,b). It should be noted that all the previously published trials which administered IGRT in SOT recipients did not distinguish patients with or without HGG, which may have diluted a possible effect.

Splenic dysfunction and complement deficiencies

The spleen is a complex lymphoid organ which is primarily responsible for defense against bloodborne encapsulated organisms and parasites. Blood is filtered through a reticular network called the red pulp, while the surrounding white pulp contains specialized

macrophages (the “reticuloendothelial system”), which remove senescent red blood cells, bacteria, and parasites, as well as lymphoid tissue, where adaptive B cell responses occur against encapsulated bacteria. The antibodies produced by these B cells opsonize bacteria and facilitate their clearance from the bloodstream.

Asplenic individuals are at risk of overwhelming bacterial sepsis (or “overwhelming post-splenectomy sepsis”). In infants under 6 months of age with congenital asplenia, this is typically due to infection with Enterobacteriaceae, especially *Escherichia coli* and *Klebsiella pneumoniae*, while in older patients and those with acquired asplenia, sepsis is typically due to encapsulated organisms including *Streptococcus pneumoniae*, *Haemophilus influenzae* type B, and *Neisseria meningitidis* (Waldman et al., 1977). They are also at risk of extraintestinal non-typhoidal *Salmonella enteritidis* infection, especially osteomyelitis and septic arthritis often seen in patients with sickle cell anemia who have autosplenectomy (Wen et al., 2017). Rarely, these patients can develop overwhelming infection with *Capnocytophaga canimorsus* or *Pasteurella multocida* after animal exposure (Zajkowska et al., 2016; Laupland et al., 2003). Finally, asplenic patients are at increased risk of severe infections with bloodborne parasites, including malaria (*falciparum* and non-*falciparum* species) and *Babesia* spp. (Ram et al., 2010).

The highest risk of sepsis in surgically splenectomized patients occurs at the extremes of age (<3 years and >50 years old) and in the first 1–3 years after splenectomy. Historically, sepsis was associated with mortality rates as high as 50%, however with preventative measures (see below), rapid recognition, and rapid initiation of antimicrobial treatment, the mortality rate post-splenectomy has dropped to as little as 1% (Lee, 2020; Madenci et al., 2019).

The complement system is a group of >20 proteins, synthesized in the liver, and organized into cascades (Classical; Alternative; or Mannose-binding lectin pathways) responsible for the opsonization and lysis of bacteria. Complement deficiencies, primarily due to genetic bases, have revealed their role in protection against encapsulated organisms and these patients develop similar infections as asplenic patients (Ram et al., 2010). However, patients with defects of the terminal membrane attack complex (MAC) are particularly predisposed to invasive and recurrent infections with *Neisseria meningitidis* and *N. gonorrhoeae*.

Causes of splenic dysfunction

Splenic function can be absent (asplenia) or diminished (hyposplenia). Asplenia can be anatomical (i.e., due to congenital absence of the spleen, surgical removal, or splenic ischemia in patients with hemoglobinopathies (autosplenectomy)), or functional (i.e., due to conditions that reduce splenic function).

The indications for surgical splenectomy are generally trauma (blunt, penetrating, and iatrogenic); refractory autoimmune cytopenias (immune thrombocytopenic purpura and autoimmune hemolytic anemia); malignancy (either primary lymphoma or metastatic solid cancers); and symptomatic massive splenomegaly, often due to hematologic disorders such as chronic myeloid leukemia (CML), myelofibrosis, and hemoglobinopathies (Browning et al., 2017). Splenectomy due to trauma is typically performed as an emergency procedure to control life-threatening bleeding and thus preoperative preparation including vaccination is not possible. For other indications, splenectomy is typically performed as an elective procedure allowing time for vaccination against encapsulated organisms (see below). When possible, partial splenectomy may be practiced in cases of trauma, benign lesions, and for symptomatic management of massive splenomegaly, thus preserving splenic function in these patients (Costi et al., 2019).

In addition to surgical splenectomy, abnormally shaped erythrocytes block splenic sinusoids resulting in multiple microinfarcts and eventually leading to a complete loss of splenic function (autosplenectomy) in children with hereditary hemoglobinopathies, mainly sickle cell anemia and hereditary spherocytosis. Patients with sickle cell disease already present evidence of hyposplenia at age 12 months and typically complete autosplenectomy by age 5 (Brousse et al., 2014).

Functional hyposplenia may result in a similar susceptibility to infection as anatomical asplenia. Celiac disease, inflammatory bowel disease, connective tissue diseases (especially SLE), human immunodeficiency virus (HIV) infection, graft-versus-host disease, splenic infiltration due to amyloidosis, hemochromatosis, and sarcoidosis, and ischemia due to splenic arterial and venous thrombosis can cause varying degrees of hyposplenia. Treatment with high dose steroids, methyl dopa, total parenteral nutrition (TPN), and splenic irradiation have also been associated with splenic dysfunction (Squire and Sher, 2020). Splenic function can be evaluated using imaging (for anatomical asplenia), the examination of a peripheral blood smear for Howell-Jolly bodies, counting of pitted red blood cells, and nuclear medicine techniques, such as spleen scintigraphy, that are more accurate than blood smear-based techniques (De Porto et al., 2010).

Causes of secondary complement deficiencies

Acquired complement deficiency can occur due to decreased production, the presence of neutralizing antibodies against a component of the complement system, or increased consumption.

Because complement proteins are produced in the liver, diseases causing liver failure result in its decreased levels, resulting in decreased bactericidal capacity, which may in part explain the occurrence of bacterial peritonitis in cirrhotic patients (Akalın et al., 1983).

Neutralizing antibodies can cause a functional defect of a complement pathway component. The monoclonal drug eculizumab is a terminal complement pathway inhibitor which binds to C5, preventing its cleavage and the formation of the MAC. It is used to treat complement-mediated diseases, including paroxysmal nocturnal hemoglobinuria (PNH), atypical hemolytic uremic syndrome (aHUS), C3 glomerulonephritis, antibody-mediated rejection (ABMR), and myasthenia gravis. Treatment with eculizumab

has been associated with an up to 10,000-fold increase in the risk of invasive meningococcal disease leading to a Food and Drug Administration (FDA) black box warning (Benamu and Montoya, 2016). Similarly, cases of disseminated gonococcal disease and even sepsis associated with eculizumab use have also been reported (Gleesing et al., 2012).

Hypocomplementemia due to consumption occurs in several rheumatological diseases, especially those associated with immune complex deposition and SLE (Hebert et al., 1991). Its clinical consequences are not well delineated. Consumption can also occur with C3 nephritic factors (C3 NeF), autoantibodies directed against the C3 convertase enzyme, which stabilize the enzyme, and lead to increased consumption of C3. This, in turn, leads to membranoproliferative glomerulonephritis (MPGN), partial lipodystrophy, and has also been associated with a predisposition to invasive meningococcal infections due to the ensuing C3 deficiency (Skattum et al., 1997). Hypocomplementemia can also occur due to loss, and has been reported in protein-losing enteropathies, usually indicated by decreases in other serum proteins (e.g., albumin, IgG) (Itoi et al., 1989).

Treatment of splenic dysfunction

The primary goal in asplenic patients is to avoid life-threatening sepsis and resulting morbidity and mortality. This is accomplished through vaccination, prophylactic and “stand-by” antibiotics and antiparasitic treatment, parasite avoidance, patient education, and rapid recognition and provision of appropriate antibiotic therapy in the emergency setting.

Asplenic patients should be vaccinated against invasive pneumococcal infection (conjugated pneumococcal vaccine followed 8 weeks later by polysaccharidic vaccine), *H. influenzae* type B vaccine, and quadrivalent and type B meningococcal vaccines. For elective splenectomy, vaccines should be administered at least 14 days, and preferably 8 weeks, before the procedure. For emergent splenectomy, vaccination should be delayed for at least 2 weeks after the procedure (Di Sabatino et al., 2011). In functional hyposplenism and asplenia, vaccines may be administered at any time due to their gradual onset and progression.

The use of prophylactic antibiotics after splenectomy is more controversial. Typical prophylactic regimens include oral penicillin V or amoxicillin; the options for penicillin allergic patients are less clear with rising pneumococcal resistance rates. In sickle cell disease patients up to age 5, randomized, controlled clinical trial evidence demonstrates an 84% reduction in infection with twice daily penicillin V and this treatment is universally recommended (Gaston et al., 1986). Similarly, chronic GVHD has been associated with invasive pneumococcal disease, likely due to the associated splenic dysfunction, and lifelong penicillin prophylaxis is recommended (Kulkarni et al., 2000). Otherwise, guidelines vary widely on which patients should start prophylaxis and when to stop it. American guidelines recommend antibiotic prophylaxis for all asplenic children under age 5 as is practiced in sickle cell disease, with 1 year of prophylactic antibiotics in children 5 years and older after splenectomy (American Academy Of Pediatrics, Committee on Infectious Diseases, 2018). British and Australian guidelines, on the other hand, recommend prophylaxis for all patients for 2 years after splenectomy, and in select groups (age under 16, splenectomy for hematologic malignancy, history of invasive pneumococcal infection) prophylaxis for life (Kanhutu et al., 2017; Davies et al., 2011). Canadian guidelines recommend antibiotic prophylaxis for at least 2 years after splenectomy in children under 5, and ideally for life depending on adherence, tolerance, and access to emergency care (Salvadori et al., 2014). Due to a lack of clear evidence in patients older than 5 years of age and outside of sickle cell disease or chronic GVHD, it is likely that guidelines will continue to be variable and that the choice of whether to initiate prophylaxis and its duration will ultimately fall to patient and clinician preference.

Other preventative measures include patient education and medical identification cards/jewellery. Good knowledge of the risk of postsplenectomy sepsis is associated with a significant reduction in the risk of invasive pneumococcal infection compared to those with poor knowledge (El-Alfy and El-Sayed, 2004). Patients are instructed to immediately seek medical care if a fever (temperature of 38.0 degrees Celsius or higher) develops. Patients who may experience delayed access to care should be prescribed a supply of “stand-by” antibiotics targeting the most likely pathogens (e.g., amoxicillin-clavulanate, or a respiratory fluoroquinolone for penicillin allergic patients) to be taken immediately if a fever develops before proceeding to medical care as soon as possible. Management of post-splenectomy sepsis is beyond the scope of this article. Asplenic travelers should also be warned of the risk of malaria and babesiosis and should observe appropriate mosquito and tick avoidance and be prescribed appropriate malaria prophylaxis for the destination. Finally, patients should be warned of the risk of *C. canimorsus* sepsis after animal bites and should be prescribed antimicrobial prophylaxis should one occur.

Treatment of acquired complement deficiencies

Complement levels are a marker of disease activity in rheumatologic disease, so treatment of the underlying disease may correct hypocomplementemia. Otherwise, prevention of infections with encapsulated organisms is the mainstay of treatment, as in splenic dysfunction. As per the product monograph, patients being treated with eculizumab should receive quadrivalent (serogroups A, C, Y, W135) meningococcal and a first dose of meningitis serogroup B vaccine at least 14 days before initiating treatment with eculizumab; if treatment cannot be delayed, oral penicillin prophylaxis is recommended until this time has elapsed. Erythromycin is recommended as an alternative for patients who are allergic to penicillin. Breakthrough infections do occur despite vaccination, so patients should be informed of the signs and symptoms of invasive meningococcal disease and counselled to immediately present for care should they develop (McNamara et al., 2017). Because of breakthrough infections, British and French guidelines recommend oral penicillin prophylaxis for the duration of treatment, with the British guidelines equally recommending that patients be further provided with a supply of “rescue” medication in the form of ciprofloxacin 500 mg to be taken immediately if fever develops (Haut Conseil De La Santé Publique, 2014; PNH National Service, 2021). It is also prudent to vaccinate against other

vaccine-preventable encapsulated organisms, namely conjugated and polysaccharidic pneumococcal vaccine and *Haemophilus influenzae* type B vaccine. Finally, given the occurrence of severe gonococcal infections during eculizumab therapy, it is prudent to counsel patients on safe sexual activity and regular screening for sexually transmitted infections.

T cell deficiencies

T cells are essential for the control of intracellular infections. Broadly, cytotoxic CD8⁺ T cells kill infected cells, while T helper (CD4⁺) cells, produce cytokines needed for many immune functions including priming professional phagocytes to destroy ingested organisms. As a result, patients with secondary T cell deficiencies develop recurrent, invasive, and persistent infections with DNA and RNA viruses, intracellular bacteria, mycobacteria, dimorphic endemic fungi, yeasts, and parasites (see Table 4).

In addition to the above opportunistic infections, RNA respiratory viruses cause persistent and severe infection in T cell immunocompromised patients, especially progression of upper respiratory tract infections (URTI) to lower respiratory tract infection (LRTI). Progression to LRTI and mortality are particularly increased in allogeneic HSCT recipients for influenza A and B, respiratory syncytial virus (RSV), parainfluenza virus 3 (PIV3), and human metapneumovirus (HMPV). Rhinovirus infrequently progresses to LRTI and the incidence of progression of bocavirus is unknown (Fontana and Strasfeld, 2019). Coronaviruses were previously thought to be quite benign; however, during the SARS-CoV-2 pandemic, compromised immunity, particularly involving T cell function, was found to predispose to severe disease (Goldman et al., 2021). On the other hand, the evidence in specific transplant populations has been mixed, with a clear association with negative outcomes seen in allogeneic HSCT and lung transplant recipients, but not definitively demonstrated in other SOT recipients (Goldman et al., 2021). The immunosuppression severity index (ISI) has been validated to predict progression from URTI to LRTI in allogeneic HSCT recipients with RSV and can be used to quantify the severity of T cell immunocompromised in this population to guide therapy (see Table 5) (Shah et al., 2014). A score of 0–2 denotes low risk; 3–6 intermediate risk; and 7–10 high risk. Moderate- and high-risk scores were associated with progression of URTI to LRTI, and high risk was associated with mortality.

Causes of secondary T cell disorders

Due to medical conditions

The medical condition most associated with secondary T cell deficiency and opportunistic infections is the acquired immune deficiency syndrome (AIDS) caused by the human immunodeficiency virus (HIV). HIV is an RNA retrovirus that selectively targets T helper (CD4⁺) cells, eventually leading to severe lymphopenia and many of the opportunistic infections described above (Sabin and Lundgren, 2013). Much of what is applied today about management of opportunistic infections in secondary T cell deficiencies has been extrapolated from studying people living with HIV (PLWH). Human T-lymphotropic virus (HTLV)-1, a retrovirus like HIV, mostly manifests as acute T cell leukemia/lymphoma (ATLL), HTLV-associated myelopathy (HAM), or dermatitis in at-risk patients. However, it has a well-known association with *Strongyloides* hyperinfection and disseminated strongyloidiasis (Porto et al., 2001; Montes et al., 2009).

T cell leukemias and lymphomas cause numerical and functional T cell deficiency due to the proliferation of an abnormal lymphoid clone, like the numerical and functional phagocyte deficiency that is encountered in AML (see above). This risk is added to the further T cell immunosuppression associated with T cell targeted therapy, chemotherapy and glucocorticoids (see below). These patients are well known to be predisposed to developing *Pneumocystis jiroveci* pneumonia, PJP (Poulsen et al., 2001). Also, thymoma has also been reported to cause a severe functional T cell deficiency distinct from Good's syndrome. While naïve T cells are numerically normal, an abnormal T cell receptor (TCR) prevents them from being activated, which leads to generalized anergy (Christopoulos et al., 2015).

Interferon- γ (IFN- γ) is a key effector cytokine produced by activated T and NK cells that primes phagocytes for killing of ingested microbes (Murphy, 2012). Acquired neutralizing anti-IFN- γ antibodies occur in older adults of Asian, particularly Southeast Asian, descent. This is associated with disseminated non-tuberculous mycobacterial (NTM) infections but has recently also been described in HIV-negative patients with otherwise unexplained *Talaromyces marneffe* infection (Browne et al., 2012; Guo et al., 2020). Idiopathic CD4 lymphopenia is defined as a T helper (CD4⁺) cell count below 300 cells mm⁻³ in HIV-negative patients; despite almost 30 years of investigation, no cause has been elucidated. These patients develop similar opportunistic infections as those with advanced HIV/AIDS (Smith et al., 1993).

Pregnancy is a relative T cell deficient state, particularly in the second and third trimesters. This state may explain the predisposition of pregnant women to invasive listeriosis, which can infect the fetus causing granulomatosis infantiseptica, and to severe primary varicella infection with a particular predisposition to developing pneumonitis which is in some cases severe enough to require mechanical ventilation (Madjunkov et al., 2017; Shrim et al., 2012).

Iatrogenic causes

T cell immunocompromised results as a side effect of alkylating and antiproliferative chemotherapy for cancer, as an intended consequence of targeted T cell depletion, and because of targeted blockade of effector cytokines by monoclonal antibodies used to treat diverse autoimmune phenomena.

Table 4 Opportunistic infections associated with T cell deficiencies.

Kingdom	Genus	Species	Manifestations
Viruses	<i>Herpesviridae</i>	Herpes simplex virus (HSV)	Mucocutaneous ulcers
			Hepatitis
			Pneumonitis
			Retinitis
			Encephalitis

Table 5 Immunosuppression severity index (ISI) for allogeneic HSCT patients with RSV.

Criterion	Points
ANC <500	3
ALC <200	3
Age >40	2
Myeloablative conditioning regimen	1
GVHD	1
Corticosteroid treatment	1

Cancer chemotherapy causes myelosuppression affecting all cell lines. Some chemotherapy agents primarily used to treat hematological malignancies are particularly T cell depleting. Fludarabine, a DNA polymerase inhibitor, has been associated with prolonged T helper (CD4⁺) cell lymphopenia and cases of PJP and CMV disease up to 1 year after treatment (Tam et al., 2004; Haeusler et al., 2013; Marchesi et al., 2018). This is compounded by the fact that it is often used in combination with the alkylating agent cyclophosphamide (also T cell depleting) and anti-CD20 monoclonal antibody rituximab (i.e., FCR regimen) to treat CLL. Similarly, the alkylating agent, bendamustine, has been associated with prolonged T helper (CD4⁺) lymphopenia and typical opportunistic infections including CMV, herpes zoster, histoplasmosis, and PJP and is also used in combination with rituximab (i.e. BR regimen) most often to treat B-cell lymphomas (Fung et al., 2019).

Some targeted therapies are also associated with significant T cell immunosuppression. Treatment with the proteasome inhibitor bortezomib, used primarily for multiple myeloma, is associated with a high incidence of zoster in the absence of prophylaxis, caused by a loss of VZV-specific T cell responses (Kim et al., 2015). The anti-CD52 antibody, alemtuzumab, used at high-doses to treat T cell malignancies, specifically targets B and T cells for destruction causing profound and prolonged T cell lymphopenia and the typically-associated opportunistic infections; this agent is also used in solid organ transplants and in hematopoietic transplant recipients requiring lymphocyte-depletion (Dearden et al., 2002; Helfrich and Ison, 2015; Coles et al., 2012). Interestingly, the ostensibly B cell targeted anti-CD20 agent rituximab and anti-CD38 agent daratumumab have also been associated with infections traditionally associated with T cell deficiency; rituximab has been associated with PML and both have been associated with hepatitis B reactivation (Focosi et al., 2019; Loomba and Liang, 2017; Lee et al., 2021). The mechanism behind this observation has yet to be determined.

Targeted T cell depletion is used to prevent and treat rejection and GVHD in SOT and allogeneic HSCT recipients, respectively, and to treat autoimmune and inflammatory diseases. SOT and some HSCT recipients require conditioning at the time of transplant to rapidly reduce the T cell population and prevent acute cell-mediated rejection (ACMR). The agents most often used are antithymocyte globulin (ATG), a polyclonal animal-derived (rabbit or horse) antibody product targeting human T cells, or alemtuzumab (discussed above). The anti-IL-2-receptor monoclonal antibodies, daclizumab and basiliximab, are also sometimes used (Swiatecka-Urban, 2003). This results in rapid and profound lymphopenia, putting patients at highest risk of opportunistic infections for the first 6 months after receiving a SOT (Fishman, 2007). Similarly, allogeneic HSCT recipients receive myeloablative conditioning with alkylating chemotherapy; the specific regimens are beyond the scope of this chapter. This is followed in both cases by maintenance immunosuppression, administered for life in SOT recipients and typically for the first 100 days after HSCT, unless acute or chronic GVHD develops (in which case, more intense and/or prolonged immunosuppressive therapy is given). The agents most used are the calcineurin inhibitors, tacrolimus or cyclosporine, which inhibit T cell activation and proliferation; mycophenolate mofetil (MMF), a purine synthesis inhibitor which prevents T cell proliferation; and glucocorticoids (discussed below) (Gaston, 2001). Other agents used are mammalian target of rapamycin (mTOR) inhibitors, rapamycin and sirolimus, and costimulation blockers (e.g., belatacept (Noble et al., 2019)). Episodes of rejection in SOT recipients may require reinduction and increased immunosuppressant dosing or addition of new maintenance agents, which increases their susceptibility to infection.

Many of the above agents may be used to treat autoimmune conditions. The first line treatment for older patients with acquired aplastic anemia, for example, is ATG induction followed by maintenance with a calcineurin inhibitor (Bacigalupo, 2017). Alemtuzumab is also used to treat multiple sclerosis, albeit with a lower dose than other indications (Coles et al., 2012). Calcineurin inhibitors, MMF, and high dose steroids are used to treat lupus nephritis, while MMF is also used for myositis associated lung disease, and vasculitides (Fanouriakis et al., 2020; Huapaya et al., 2019). Other T cell antiproliferative agents frequently used to treat autoimmune diseases are methotrexate, a folate synthesis inhibitor, azathioprine, a synthetic purine analogue, and fingolimod, which sequesters T cells in lymphoid tissues.

Glucocorticoids are broad spectrum immunosuppressants used for their anti-inflammatory effect in autoimmune conditions, prevention, and treatment of rejection in SOT, treatment of acute GVHD, and a variety of neurological, cardiac, pulmonary, gastrointestinal, rheumatologic, and allergic conditions. They are also used in combination chemotherapy regimens for lymphoma and multiple myeloma, as well as for prevention of post-chemotherapy emesis. High-dose and prolonged glucocorticoid therapy are variously defined by different authors, but a consensus exists for 30 mg of prednisone equivalent per day for 1 month or greater (Buttgereit et al., 2002). The T cell suppressive effect of glucocorticoid therapy is additive to other immunosuppressants and increases the risk of opportunistic infection, particularly PJP, CMV infection, tuberculosis, and *Strongyloides* hyperinfection (Malpica and Moll, 2020).

T helper (CD4⁺) cells exert their influence on professional antigen-presenting cells through the production of cytokines at the immunological synapse. Biologic immunosuppressants are targeted monoclonal antibodies and small molecules that prevent cytokines from binding to their target or interfere with downstream receptor signaling. These medications are now broadly used to treat rheumatological, dermatological, gastrointestinal, neurological, and ocular autoimmune diseases, but are also associated with opportunistic infections because of the functional T cell deficiency they create (see Table 6).

The longest marketed, and thus best studied, of the biologic immunosuppressants are the TNF- α inhibitors. These are associated with an increased risk of active tuberculosis, non-tuberculous mycobacterial disease, histoplasmosis, PJP, candidiasis, herpes zoster, hepatitis B reactivation, *Legionella* pneumonia, invasive *Listeria monocytogenes*, *Salmonella* spp., and pneumococcal disease; the association between TNF- α inhibition and progression of hepatitis C infection is controversial (Pompili et al., 2013; Brode et al., 2015; Dixon et al., 2010; Vallabhaneni and Chiller, 2016; Strangfeld et al., 2009; Baddley et al., 2018). The anti-TNF- α monoclonal antibodies appear to present a greater risk of infection than the soluble TNF- α receptor etanercept (Tubach et al., 2009). Non-TNF- α -targeted biologic immunosuppressants appear to cause less susceptibility to infection; however, population-level data is sparse, as many of these agents have been recently marketed (Cantini et al., 2017; Pettipher and Benitha, 2020). Nonetheless, their monographs carry the same warnings as TNF- α inhibitors.

Table 6 Biological immunosuppressants and their targets.

<i>Mechanism</i>	<i>Drug</i>	<i>Approved indications</i>
Anti-TNF- α monoclonal antibody	Infliximab	Rheumatoid arthritis
	Adalimumab	Juvenile idiopathic arthritis
	Certolizumab	Psoriatic arthritis
	Golimumab	Ankylosing spondylitis Plaque psoriasis Crohn's disease Ulcerative colitis
TNF- α soluble receptor	Etanercept	Rheumatoid arthritis
		Juvenile idiopathic arthritis
		Psoriatic arthritis
		Ankylosing spondylitis Plaque psoriasis Crohn's disease Ulcerative colitis
Anti-IL-1 monoclonal antibody	Anakinra	Rheumatoid arthritis Cryopyrin-associated periodic syndromes
	Canakinumab	Cryopyrin-associated periodic syndromes Tumor Necrosis Factor Receptor Associated Periodic Fever Syndromes (TRAPS) Hyperimmunoglobulin D Syndrome/Mevalonate Kinase Deficiency Familial Mediterranean Fever Systemic Juvenile Idiopathic Arthritis
Anti-IL-6-monoclonal antibody	Tocilizumab	Rheumatoid arthritis
		Giant Cell Arteritis
		Polyarticular Juvenile Idiopathic Arthritis
		Systemic Juvenile Idiopathic Arthritis Cytokine release syndrome
JAK inhibitor	Tofacitinib	Rheumatoid arthritis
		Psoriatic arthritis Ulcerative colitis
Costimulatory modulator	Abatacept	Rheumatoid arthritis
		Juvenile idiopathic arthritis Psoriatic arthritis
Anti-IL-17 monoclonal antibody	Ixekizumab	Plaque psoriasis Psoriatic arthritis
	Secukinumab	Plaque psoriasis Psoriatic arthritis
		Ankylosing spondylitis
	Brodalumab	Plaque psoriasis
IL-12/23 antagonist	Ustekinumab	Plaque psoriasis Psoriatic arthritis Crohn's disease
IL-23 antagonist	Guselkumab	Plaque psoriasis
Integrin inhibitor	Natalizumab	Multiple sclerosis
	Vedolizumab	Ulcerative colitis Crohn's disease

Cadherin inhibitors block trafficking of autoreactive T cells to sites of disease activity. Thus, the T cell immunodeficiency they create is thought to be localized to the site of action. The cadherin inhibitors, natalizumab (originally used for multiple sclerosis and inflammatory bowel disease) and efalizumab (originally used for psoriasis, now withdrawn from the market), were both associated with an extremely high incidence of progressive multifocal leukoencephalopathy (PML) caused by the blockade of lymphocyte trafficking to the CNS (Ho et al., 2017; Schwab et al., 2012). Vedolizumab selectively blocks lymphocyte trafficking to the gut and is used to treat inflammatory bowel disease (IBD); it has not been associated with any cases of PML to date, but nonetheless carries an FDA black box warning. It has been associated, however, with an increased risk of CMV colitis, presumably due to localized T cell immunodeficiency within the gut (Hommel et al., 2018).

Treatment of secondary T cell dysfunction

The mainstay of treatment of secondary T cell dysfunction is reversal of immunosuppression through treatment of the underlying disease, or reduction of iatrogenic immunosuppression (RIS) when this is possible. Vaccination and antimicrobial prophylaxis are also used to prevent opportunistic infections (OIs). Biological response modifiers and adoptive T cell therapy are emerging treatments for refractory OIs.

Reversal of immunosuppression

Restoration of T cell function is critical for the elimination of OIs. In PLWH, initiation of highly active antiretroviral therapy (HAART) suppresses viral replication and at least partially restores T helper (CD4⁺) cell counts and function (Masur et al., 2014). In patients with autoimmune diseases, temporary or permanent suspension or replacement of immunosuppressive therapy is often practiced when infections develop; however, this must be balanced against disease activity. The balance between RIS and prevention of cell-mediated rejection is difficult in SOT recipients; severe or refractory OIs may require sacrificing a non-critical organ (for example a kidney allograft), although this is not possible in critical organs such as liver, heart, and lung grafts. In allogeneic HSCT, delayed engraftment or treatment of life-threatening acute GVHD may make restoration of T cell function impossible. In patients with anti-IFN- γ autoantibodies, rituximab or daratumumab has been successfully used to restore IFN- γ and clear NTM infections (Czaja et al., 2014; Ochoa et al., 2021).

Clinicians must also balance RIS with the risk of the immune reconstitution inflammatory syndrome (IRIS). IRIS takes two forms: paradoxical IRIS occurs when a seemingly improving opportunistic infection suddenly flares due to restoration of immunity and an inflammatory infiltrate, while unmasking IRIS reveals a previously undetected OI in the setting of immune recovery (Barber et al., 2014). The treatment of IRIS generally includes steroids for their anti-inflammatory effect while otherwise continuing both anti-infective therapy and immune reconstitution. Certain infections, particularly CNS tuberculosis and cryptococcosis, cause life-threatening IRIS due to increased intracranial pressure (ICP) and delayed initiation of HAART is associated with improved survival in these patients; how this applies to non-HIV patients is unknown (Török et al., 2011; Boulware et al., 2014). The evidence for prophylactic steroids to prevent IRIS is mixed; they appear to be beneficial in HIV-infected patients with tuberculosis and moderate-to-severe PJP, but not in cryptococcal meningitis (Meintjes et al., 2018; Bozzette et al., 1990; Beardsley et al., 2016; Immunocompromised Host Society, 1990). Again, it is unclear how these data apply to non-HIV T cell immunocompromised patients.

Vaccination

Live vaccines are contraindicated in patients with T cell deficiencies as there is a risk of the vaccine strain acquiring virulence and causing infection. If iatrogenic immunosuppression is planned, it is recommended to ensure that all live vaccines are up to date before it is initiated. Specifically, a waiting period of 4 weeks after receiving the measles-mumps-rubella vaccine (MMR) and 6 weeks after receiving the live varicella or herpes zoster vaccine should be observed before administering T cell immunosuppression.

Conjugated and polysaccharidic vaccines are safe in patients receiving T cell-depleting therapies, but their efficacy may be reduced once on therapy (Papp et al., 2019). As such, it is preferable to administer these vaccines before planned iatrogenic immunosuppression. Both conjugated and polysaccharidic pneumococcal, human papillomavirus (HPV, depending on the patient's age), and HBV vaccination are recommended pre-immunosuppression; it is also good practice to update protection against diphtheria, pertussis, and tetanus, particularly if the patient has not received acellular pertussis vaccine. Annual influenza vaccination is also recommended (Danziger-Isakov and Kumar, 2019). For patients who are already immune to varicella, evidence is emerging that the herpes zoster adjuvanted recombinant subunit vaccine (Shingrix) may be immunogenic and possibly provide protection against herpes zoster post-renal transplant and autologous HSCT (Vink et al., 2020; Bastidas et al., 2019).

Patients who undergo allogeneic HSCT receive a new immune system, hence, they must recommence vaccination with a primary series after the transplant and should not be considered immune to any virus, especially varicella zoster, despite previous infection or vaccination history. Vaccination with conjugate or polysaccharidic vaccines may commence 3–6 months after transplant and live vaccination may commence 24 months after transplant, if there is adequate engraftment, disease control, and lack of GVHD (Kamboj and Shah, 2019).

Antimicrobial prophylaxis

Screening and treatment of latent infections can prevent reactivation and disseminated disease. In patients starting treatments that risk HBV flares or reactivation, serology for hepatitis B surface antigen (HBsAg), indicating chronic infection, and hepatitis B core antibody, indicating resolved infection, should be performed. Patients who are chronically infected with or who have been previously exposed to HBV and are starting high-risk regimens (>10% risk of reactivation) should be started on prophylaxis with tenofovir or entecavir and be monitored regularly for HBV reactivation or hepatocyte injury; those starting moderate-risk regimens (1–10% risk of reactivation) may be monitored without prophylaxis (Myint et al., 2020). Serological and nucleic acid amplification test (NAAT)-based screening for HCV can also be performed followed by treatment of chronically infected patients with direct acting antivirals (DAAs). Screening for latent tuberculosis infection (LTBI) should be performed in those at epidemiological risk with tuberculin skin testing (TST) or an IFN- γ release assay (IGRA); treatment of LTBI with 4 months of rifampin as compared to 9 months of isoniazid (INH) is better tolerated and has better completion rates in both adults and children (Menzies et al., 2018; Diallo et al., 2018; Gardam et al., 2003). Note that patients who are already T cell deficient may be generally anergic resulting in false-negative or indeterminate LTBI screening test results. Screening for chronic strongyloidiasis with serology or stool culture and treatment with ivermectin is also recommended in patients born in or who have lived in endemic countries (Requena-Méndez et al., 2017).

CMV risk in hematopoietic and SOT recipients is stratified by the donor/recipient (D/R) serostatus; the type of organ transplanted; and the induction regimen: this risk assessment is used to determine whether to administer primary prophylaxis with valganciclovir, or to monitor for CMV reactivation and initiate pre-emptive treatment should this occur. In SOT recipients, the

D/R serostatus with highest risk is donor positive/recipient negative (D+/R-), whereas donor positive/recipient positive (D+/R+) and donor negative/recipient positive (D-/R+) statuses are considered intermediate risk, while donor negative/recipient negative (D-/R-) is considered low risk. The most vascularized organs are at highest risk of transmitting donor derived CMV, including lung, facial composite, and small bowel transplants. Lymphocyte-depleting induction with alemtuzumab and ATG also increase the risk of reactivation (Razonable and Humar, 2019). Patients who do receive valganciclovir prophylaxis are treated for 100 days after SOT, which is the period of maximal immunosuppression; they must still be monitored for CMV reactivation after this period, as infection (viremia) and/or end-organ disease can occur after prophylaxis.

Patients receiving chemotherapy, targeted therapies, or HSCT for hematological malignancies, and who are at high risk of HSV and VZV reactivation, are usually prescribed acyclovir or valaciclovir prophylaxis for the duration of the at-risk period. In HSCT recipients, the risk stratification for CMV reactivation is different from SOT, with D-/R+ status conferring the highest risk of CMV reactivation, D+/R- and D+/R+ status conferring intermediate risk, and D-/R- conferring the lowest risk. CMV prophylaxis in this population is more complex, as ganciclovir prophylaxis has been associated with delayed engraftment and an increased incidence of bacterial and fungal infections; it is thus not used routinely for this indication (Boeckh and Ljungman, 2009). However, the novel CMV antiviral agent letermovir, a terminase complex inhibitor that is not myelosuppressive, has been found to significantly reduce CMV reactivation in allogeneic HSCT recipients when administered until 14 weeks after transplant and has been approved for CMV prophylaxis in this population (Marty et al., 2017).

PJP prophylaxis is used to prevent pneumocystis pneumonia in PLWH with T helper (CD4⁺) counts below 200 cells mm⁻³; patients receiving high-risk chemotherapy regimens; allogeneic HSCT recipients and SOT recipients for the first 6 months post-transplant, or longer if being treated for acute GVHD or rejection; and patients receiving high-dose, prolonged glucocorticoid treatment, often in combination with a second immunosuppressant (Masur et al., 2014; Maertens et al., 2016). Recommended regimens for PJP prophylaxis can be found in Table 7.

Primary prophylaxis against toxoplasmosis is indicated in seropositive PLWH with T helper (CD4⁺) cell counts below 100 cells mm⁻³; the usual agents are daily double-strength sulfamethoxazole-trimethoprim, dapsone combined with pyrimethamine, or daily atovaquone. These patients should also be screened once with serum cryptococcal antigen and, if investigations reveal no pulmonary or CNS disease, receive fluconazole prophylaxis (Masur et al., 2014). PLWH living in hyperendemic regions for histoplasmosis also receive daily itraconazole prophylaxis until their T helper (CD4⁺) cell counts rise above 150 cells mm⁻³; neither of these recommendations has been applied outside of the HIV setting (Masur et al., 2014). In regions endemic for coccidioidomycosis, seronegative PLWH and SOT recipients are regularly screened for seroconversion (one or twice per year) and treated with fluconazole if this occurs (Nanayakkara and Blodgett, 2019).

Immunotherapies

Recombinant cytokine therapies can be used to boost T cell numbers, strengthen their response, or pharmacologically replace cytokines that they normally produce. T cells may be stimulated to proliferate using recombinant IL-2, which is approved for use as a cancer immunotherapy; however, it also increases the proliferation of T regulatory cells (Tregs) and causes dose-dependent fever, chills, and vascular leak, which limit its efficacy and tolerability (Mitra and Leonard, 2018). T cell numbers can also be boosted through mobilization from the bone marrow and thymus by recombinant IL-7, as has been successfully done in idiopathic CD4 lymphopenia and may potentially be applied to other patients with reduced T helper (CD4⁺) cell counts (Sheikh et al., 2016). Recombinant IFN- γ in pharmacological doses replaces effector cytokine production and stimulates phagocytes to kill intracellular pathogens; while this has been used successfully in patients with chronic granulomatous disease and in a case report of disseminated NTM infection in the setting of anti-IFN- γ autoantibodies, systemic side effects again limit its tolerability (Vignesh et al., 2017; Harada et al., 2021).

Adoptive T cell transfer is an emerging treatment with the potential to revolutionize the management of OIs in patients with secondary T cell immunodeficiencies. This involves the ex vivo expansion of autologous or third-party T cells specific for the infection to be treated followed by infusion into the patient. The largest trial to date administered an off-the-shelf, five-valent product (specific for CMV, EBV, HHV-6, BK virus, and adenovirus) to 38 allogeneic HSCT recipients, resulting in a partial or complete clinical response rate of 92% after the first infusion (Tzannou et al., 2017). A phase 3, multicenter trial to treat

Table 7 Recommended regimens for PJP prophylaxis.

Drug	Route	Dosing	Limitations
Sulfamethoxazole-trimethoprim	Oral	1 single-strength tablet daily 1 double-strength tablet daily 1 double-strength tablet three times per week	Myelosuppression, hyperkalemia, allergy
Dapsone	Oral	100 mg daily	Hemolytic anemia in G6PD deficiency
Atovaquone	Oral	1500 mg daily	Cost, efficacy
Pentamidine	Inhalation	300 mg monthly	Inconvenience of administration, breakthrough infection in upper lobes

hemorrhagic cystitis using this product is ongoing ([clinicaltrials.gov NCT04390113](https://clinicaltrials.gov/ct2/show/study/NCT04390113)). Cell therapy is also an emerging treatment for invasive fungal disease. Cells targeting *Candida* spp., *Aspergillus* spp., and *Rhizopus oryzae* have been successfully manufactured and have shown in vitro activity against these agents (Lum and Bollard, 2018). In a single-center study in patients post-hematopoietic stem cell transplant (HSCT) with confirmed invasive aspergillosis, adoptive T cell transfer resulted in clearance of both serum antigenemia and infection in 9 out of 10 treated patients, versus 7 out of 13 controls (Perruccio et al., 2005). One of the challenges in integrating cell therapies into clinical practice is the effect of ongoing iatrogenic immunosuppression for GVHD or SOT rejection on these products; however, recent publications have reported genetically engineered virus-specific T cell products that are resistant in vitro to glucocorticoids, tacrolimus, MMF, and alemtuzumab, essentially creating cells that are “armored” against these immunosuppressants (Kaeuferle et al., 2020; Hafezi et al., 2020; Amini et al., 2021; Poirot et al., 2015).

Conclusion

SIDs are common in clinical practice and are likely to become more common as pharmacological and cell therapies expand in scope. A solid understanding of the affected arm of the immune system is required to recognize the associated infectious risks associated with medical conditions and immunosuppressant therapies and to intervene early to treat OIs. Unfortunately, antimicrobial therapy is often not sufficient to eliminate these OIs, and clinicians also need to understand the immunological tools at their disposal to restore immunity whenever possible. Immunologically targeted interventions including recombinant cytokines, antibodies, and cell therapies are likely to take a greater role in the treatment of these infections in the years ahead.

Introduction

Inflammation is a normal response to infection and tissue damage, aiming to eliminate the pathogens and facilitate tissue repair. Errors in one or more elements of innate immunity led to spontaneous or chaotic immune activation, with excessive production of pro-inflammatory cytokines, which in turn lead to prolonged and persistent activation of immune cells, causing systemic and organ-specific autoinflammation. Autoinflammatory diseases (AIDs) are the heterogeneous group of disorders characterized by chronic or intermittent systemic and organ-specific inflammation and recurrent fever caused by dysregulation of the innate immune system, also known as “periodic fevers.” The term “autoinflammatory diseases” was introduced in 1999 by Michael McDermott and Daniel Kastner et al. They reported the genetic cause for the systemic inflammation in tumor necrosis factor (TNF) receptor-associated periodic syndrome (TRAPS) in the absence of classic autoimmune features. AIDs are usually linked to a mutation and epigenetics affecting a broad spectrum of innate immune pathways, including inflammasome function, aberrant recognition of host molecules by TLRs, nuclear factor kappa B (NF-κB) activation, and type I interferon production, which may trigger sterile inflammation. Depending on the error, the clinical presentation varies between individual syndromes. Common findings associated with AIDs are episodic fever, rash, swelling of joints, and overproduction of IL-1β. Thus, IL-1β has become a common therapeutic target. Due to its rarity and a relatively small number of patients with the particular autoinflammatory disorder, evidence-based guidelines are lacking. The treatment is usually based on individual centers’ experience or expert’s opinion. Almost 10 years ago, in 2012, few European pediatric centers experienced in rheumatic diseases launched a project called SHARE (Single Hub and Access point for pediatric Rheumatology in Europe) with one of its main aims to create evidence-based recommendations for the management of the pediatric rheumatic diseases. Among the three leading monogenic AIDs were found: cryopyrin-associated periodic syndromes (CAPS), tumor necrosis factor receptor-associated periodic syndrome (TRAPS), and mevalonate kinase deficiency (MKD) (Ter Haar et al., 2015). Additionally, in 2015, the European Alliance of Associations for Rheumatology (EULAR) published guidelines for managing familial Mediterranean fever. Due to the increasing number of known AIDs, available recommendations seem to be a drop in the ocean for the physicians who treat these specific disorders.

Due to the availability of new treatment methods, AIDs management is transforming from strictly symptomatic, including antipyretics, corticosteroids, and non-steroid anti-inflammatory drugs (NSAIDs), to more specific and targeted. AIDs respond favorably to the appropriate treatment. Colchicine is highly effective in familial Mediterranean fever (FMF), anti-interleukin (IL)-1 therapies in cryopyrin-associated periodic syndromes (CAPS), and tumor necrosis factor receptor-associated periodic syndrome (TRAPS). Medications such as anakinra, rilonacept, and canakinumab have revolutionized the treatment of AIDs (Table 1).

Leading groups of drugs used in the treatment of AIDs

Colchicine

Colchicine is an alkaloid initially extracted from bulbs of two plants of the Lily family: *Colchicum autumnale* (meadow saffron) and *Gloriosa superba*. In the form of the autumn crocus, it was used to treat joint swelling since approximately 1500 BCE (Wall, 2015). Its

Table 1 Treatment of autoinflammatory diseases—summary.

<i>Monogenic diseases</i>		<i>Treatment</i>
Interleukin-1—mediated disorders	Familial Mediterranean Fever (FMF)	Colchicine Canakinumab Anakinra
	Tumor necrosis factor receptor-associated periodic syndrome (TRAPS)	Glucocorticoids Canakinumab Etanercept
	Cryopyrin-associated periodic syndrome (CAPS)	Interleukin-1 antagonists (canakinumab, anakinra, rilonacept)
	Mevalonate kinase deficiency (MKD/HIDS)	Non-steroid anti-inflammatory drugs Canakinumab Anakinra Etanercept Tocilizumab
	Deficiency of the interleukin-1-receptor antagonist (DIRA) Majeed syndrome	Anakinra Non-steroidal anti-inflammatory drugs Glucocorticoids Anakinra Bisphosphonates TNF- α inhibitors RBC transfusions Physical therapy
	Autoinflammation with infantile enterocolitis	Anakinra
	Blau syndrome	Glucocorticoids Methotrexate TNF- α inhibitors Canakinumab
	NLRP12-associated autoinflammatory disorder	Non-steroidal anti-inflammatory drugs Antihistamines Glucocorticoids Anakinra TNF- α inhibitors
	CARD-14 mediated psoriasis	Ustekinumab Ixekizumab
	Deficiency of IL-36 receptor antagonist	Glucocorticoids Cyclosporine Acitretin Granulocyte/monocyte apheresis Adalimumab Anakinra Antibiotics Diet Vitamin supplementation Immunoglobulin replacement therapy TNF- α inhibitors
NF- κ B—mediated disorders		
Interferon-mediated disorders	Haploinsufficiency of A20 Otlipenia Aicardi-Goutières syndrome	Glucocorticoids Azathioprine Intravenous immunoglobulin Reverse transcriptase inhibitors
	Proteasome-associated autoinflammatory syndrome	Glucocorticoids Immunosuppressive agents Anakinra Tocilizumab TNF- α inhibitors JAK-inhibitors (baricitinib) JAK inhibitors
		Glucocorticoids TNF- α inhibitors Anakinra Canakinumab Cyclosporine Tacrolimus Intravenous immunoglobulin Thalidomide Dapsone
Unknown pathogenetic mechanism	STING-associated vasculopathy with onset in infancy Pyogenic arthritis, pyoderma gangrenosum and acne syndrome (PAPA)	Glucocorticoids TNF- α inhibitors Anakinra Canakinumab Cyclosporine Tacrolimus Intravenous immunoglobulin Thalidomide Dapsone

active pharmacological component was isolated in 1820 and in 1833 purified and named colchicine. In 1972 Goldfinger described the colchicine use in five patients with familial Mediterranean fever, which resulted in a spectacular reduction of the number of attacks ([Goldfinger, 1972](#)). Colchicine anti-inflammatory properties base on few phenomena:

- It binds to tubulin inside leukocytes, formatting tubulin-colchicine complex, which results in chemotaxis inhibition (tubulin is a microtubule component—its abnormal structure results in disability to move);
- Reduces TNF α production by macrophages and its receptors on endothelial cells—which prevents neutrophils from binding to adhesion molecules on the epithelium;
- Reduces phagocytosis, lysosomal enzyme release, and phospholipase A2 activity
- Suppresses the activation of caspase 1, the element of NLRP3 inflammasome with a subsequent disability to activate the IL-1 β ([Soriano et al., 2020](#)).

Colchicine is metabolized in the liver via CYP3A14; thus, its administration with macrolides, azoles, or statins (or other drugs that inhibit this isoenzyme) may result in elevated plasma concentration resulting in severe complications. The symptoms of intoxication may also occur in patients with renal or liver insufficiency ([Niel and Scherrmann, 2006](#)).

According to the 2016 EULAR guidelines, colchicine effectively prevents FMF attacks and long-term consequences as amyloidosis. The treatment should be started as soon as the diagnosis is established. The initial dose recommended:

- 1–1.5 mg/day (1.8 mg/day if there are tablets 0.6 mg available) in children >10 years and adults
- 0.5–1 mg/day (1.2 mg/day if there are tablets 0.6 mg available) in children 5–10 years
- ≤ 0.5 mg/day (0.6 mg if there are tablets 0.6 mg available) in children <5 years old.

Colchicine can be given in single or divided doses, depending on individual tolerance. Due to gastrointestinal side effects (including cramping, stomachache, diarrhea, vomiting), treatment can be started in subclinical dose (0.5 mg/day) and increased gradually in divided daily doses until the full dose is achieved.

Colchicine can be used as a diagnostic tool when the FMF is highly suspected. In this case, after starting treatment, the patient should be carefully observed for 3–6 months with monitoring of attack severity and frequency.

Suppose adherence is confirmed and the attacks still occur, or the inflammation is detected. In that case, the drug dose may be increased up to a daily dose of 2 mg/day in children and 3 mg/day in adults with careful monitoring of side effects or a maximal well-tolerated dose. If a compliant patient does not respond to treatment after 6 months, it should qualify them as non-responder or colchicine resistant. In this group of patients, it is justified to start therapy with biological agents.

Colchicine toxicity should be checked every 6 months, including liver and kidney function, complete cell blood count, creatinine phosphokinase activity, and general urine testing to detect proteinuria. Drug response is monitored using C-reactive protein and serum amyloid A concentration.

Colchicine is considered safe and should not be discontinued during conception, pregnancy, and lactation ([Niel and Scherrmann, 2006](#)).

Colchicine lifelong prophylaxis prevents attacks of FMF and amyloidosis ([Rigante, 2017](#)).

Colchicine was shown effective in idiopathic acute and recurrent pericarditis, according to Cochrane data review. Also, the COPE trial and ICAP trial confirmed a significant difference in favor of the colchicine treatment ([Blank and Lorenz, 2019](#)).

The use of colchicine in other AID is limited. It has shown partial effectiveness in TRAPS, resulting in partial improvement in 71% of cases with a complete remission in 12.5% ([Vitale et al., 2020](#)). In PFAPA patients, colchicine was found effective in reducing

attack frequency. Preliminary data suggested its use in children who did not respond to tonsillectomy, with atypical PFAPA syndrome, and in cases with predominant aphthous stomatitis (Gaggiano et al., 2019). It was not effective in patients with CAPS and HIDS/MKD (Soriano et al., 2020).

Non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs are widely used in AID mainly as symptomatic treatment. Some patients present complete reduction of symptoms after receiving only NSAIDs according to Eurofever Registry, but it is a small fraction: 8% of FMF and TRAPS, 13% of HIDS, 6% of CAPS, and 4% of PFAPA patients. NSAIDs, alone or combined with other drugs like glucocorticoids, seem to be effective in up to 80% of all cases (Ter Haar et al., 2013).

Glucocorticosteroids

Glucocorticosteroids decrease the production and action of many pro-inflammatory cytokines as well as leukocyte migration. By disrupting the function of endothelium and fibroblasts, steroids reduce the acute and chronic symptoms of inflammation like swelling, pain, or fibrosis. By blocking the NF- κ B signal sending, glucocorticoids promote anti-inflammatory proteins and suppress pro-inflammatory cytokines.

In FMF, glucocorticoids are effective in patients who do not respond to colchicine alone. Combination of these two drugs can give positive results in the majority of patients, according to Eurofever Registry (Ter Haar et al., 2013). Intravenous methylprednisolone is effective in decreasing pain and fever during attacks (Erken et al., 2008). In FMF, patients with protracted febrile myalgia symptoms can be controlled by high-dose steroids, administered intravenous or oral (Ozen et al., 2016).

In TRAPS, glucocorticoids are helpful as a short therapy during the attacks at a dose of 1 mg/kg/day. Unfortunately, this therapy neither changes the frequency of the attacks nor decreases the subclinical inflammation between them (Ter Haar et al., 2013). Sometimes in TRAPS patients, long-term treatment is necessary to control disease symptoms. Glucocorticoids are not indicated in this situation due to their side effects (Ozen et al., 2016).

In patients with hyperimmunoglobulin D syndrome (HIDS)/mevalonate kinase deficiency (MKD) and cryopyrin-associated periodic syndromes (CAPS), high doses of glucocorticoids may be beneficial during the attacks (about in 73% of HIDS cases and 80% of CAPS cases). However, the vast majority will achieve only partial remission of symptoms. Complete improvement was observed only in 9% of HIDS patients. Like in TRAPS patients, corticosteroids do not affect the frequency of the attacks (Ter Haar et al., 2013).

In contrast, glucocorticoids are the first-line treatment in PFAPA syndrome as one dose can stop the attack and fully resolve the symptoms. This enormous corticosteroid efficacy can be considered as a diagnostic test (Ter Haar et al., 2013). The usual dose is 0.5–2 mg of prednisone (or equivalents) in a single dose. Sometimes additional doses may be necessary (Ter Haar et al., 2013; Manthiram et al., 2017). The treatment with glucocorticoids was found to increase the frequency of the attacks in 25–50% of patients with PFAPA syndrome (Ter Haar et al., 2013).

Glucocorticoids are used in Blau syndrome, mostly in combination with biological agents and methotrexate (Matsuda et al., 2020). The oral treatment was also promising in proteasome-associated autoinflammatory syndrome, but it was concluded that it reduces only part of the inflammatory reactions in this group of patients (McDermott et al., 2015).

Glucocorticoids were often used to achieve symptom control in idiopathic recurrent pericarditis, but long-term follow-up showed that this treatment could increase the risk of recurrent attacks. Actual guidelines support the statement that glucocorticoids may be used only for patients who did not respond to NSAIDs with colchicine. In this group, prednisolone (0.25–0.5 mg/kg/day) should be offered, with slow tapering after 4 weeks of treatment with a full dose (Imazio et al., 2017).

In Behçet syndrome, glucocorticoids are used as a second-line treatment, according to EULAR guidelines. The choice of drug and its dose is dependent on the involved area and previous treatment (Hatemi et al., 2018).

Interleukin-1 blockers

Interleukin-1 is a potent pro-inflammatory agent, activating the cascade of inflammatory reactions via IL-1 receptor, present on almost every human cell. IL-1 receptor inhibitor was described approximately 30 years ago, and since then, there were many trials conducted with confirmed efficacy of IL-1 blockers, mainly in inflammasomopathies, where this treatment remains the most specific. It is also used when the first-line treatment is not sufficient.

Anakinra

Anakinra is a recombinant human IL-1 receptor antagonist (rhIL-1Ra) which acts as a competitive inhibitor with IL-1 α and IL-1 β , binding to the IL-1 receptor type 1 and acting similarly as endogenous IL-1Ra.

Anakinra is used in the treatment of rheumatoid arthritis, Still disease (including systemic juvenile idiopathic arthritis and adult-onset Still disease), in the United States, it was approved for the treatment of CINCA/NOMID, in Europe—for the treatment of CAPS. Anakinra efficacy was also confirmed in clinical trials in patients with FMF, TRAPS, and HIDS/MKD but was not registered for use in these diseases.

The initial dose is 0.5–2 mg/kg/day subcutaneously in children and 100 mg/day in adults. The dose may need to be gradually increased up to 5–8 mg/day to maintain remission in children. The most common side-effects reported were local reaction in the injection site, higher susceptibility to respiratory tract infection, and serious skin infections. The drug seems to be safe in pregnancy (Soriano et al., 2020).

According to EULAR recommendations, in cases of FMF refractory to colchicine, anakinra is recommended. Also, protracted febrile myalgia may be an indication of this treatment (Ozen et al., 2016). In clinical trials, anakinra treatment resulted in complete remission in 76.5% of patients with FMF, and in patients with amyloidosis, it reversed the proteinuria (Van der Hilst et al., 2016).

In the Eurofever registry, anakinra was shown beneficial in approximately 90% of TRAPS patients, and complete remission was achieved in 67% of them. The efficacy was shown in continuous and on-demand treatment. In HIDS/MKD patients described in the Eurofever registry, anakinra treatment resulted in relieving the symptoms in 84% of them, and complete remission was achieved in 29% (Ter Haar et al., 2015).

Basing on a long-term open-label control study of 18 CINCA/NOMID patients treated with anakinra (symptoms and inflammation markers improved in all), the drug was registered for CAPS treatment by the FDA and EMA (Goldbach-Mansky et al., 2006).

There is little evidence of anakinra efficacy in PFAPA syndrome resistant to glucocorticoids. In a small group of patients, anakinra prevented the disease flares (Stojanov et al., 2011).

Anakinra was also considered a treatment of proteasome-associated autoinflammatory syndrome, but the improvement in patients receiving this treatment was only transient (McDermott et al., 2015).

Anakinra is the most common treatment for Schnitzler syndrome and is recommended as the first-line drug as its long-term effectiveness was confirmed in a multicentric retrospective cohort study (Gusdorf and Lipsker, 2017).

Canakinumab

Canakinumab is a humanized IgG1 monoclonal antibody against IL-1 β . It is registered for the treatment of CAPS in children and adults, FMF, TRAPS, and HIDS/MKD. Additionally, in the United States, it is also registered to treat systemic juvenile idiopathic arthritis and Still disease in Europe—in gouty arthritis (De Benedetti et al., 2018; Soriano et al., 2020).

Canakinumab is administered subcutaneously, in children 2–4 mg/kg, in adults ≥ 150 mg every 4–8 weeks. In patients with more severe phenotypes of AID, higher doses may be necessary. In CINCA/NOMID, the dosage may be increased up to 8 mg/kg every 4 weeks, in FMF, TRAPS, and HIDS/MKD, the initial dose is usually 2 mg/kg in children or 150 mg in adults, and it can be increased up to 4 mg/kg in children and 300 mg every 4 weeks in adults.

Safety data for canakinumab during pregnancy is lacking. One series of pregnant patients treated with canakinumab showed no adverse events in seven from eight patients (Youngstein et al., 2017). Frequent side-effects during treatment with canakinumab include respiratory tract and urinary tract infections, neutropenia, and thrombocytopenia (Ridker et al., 2017; Soriano et al., 2020).

Canakinumab was proven safe and effective in patients with FMF—reduced the number of flares and decreased the concentration of acute-phase proteins, and it is approved by the Food and Drug Administration (FDA) and European Medicines Agency (EMA) (Gül et al., 2015).

According to the CLUSTER trial, canakinumab was very effective in TRAPS patients inducing partial or complete response, reducing the number of attacks, and decreasing the CRP and SAA concentrations. A similar response was documented in HIDS/MKD patients in this trial—thus, the canakinumab was approved by the FDA and EMA to treat TRAPS and HIDS/MKD (De Benedetti et al., 2018).

Canakinumab induces remission in 75–90% of patients with CAPS, the Euro fever registry showed (Ter Haar et al., 2013). There were also two cases reported (pediatric and adult) of PFAPA syndrome with an excellent response to the treatment with canakinumab in a standard dose (Soriano et al., 2020).

A randomized placebo-controlled study with canakinumab showed its efficacy in patients with Schnitzler syndrome—the reduction of clinical symptoms as well as the decrease of inflammation markers were observed. The level of complete remission in patients treated with IL-1 blockers was 83%. (Gusdorf and Lipsker, 2017).

Rilonacept

Rilonacept is a dimeric fusion glycoprotein composed of Fc part of human IgG1 and the human IgG1 receptor extracellular elements. It binds IL-1 α and IL-1 β . Based on two phase-III clinical trials results, rilonacept was considered safe and effective in adults with CAPS (Hoffman et al., 2012). The drug received registration for use only in the United States.

Rilonacept is given subcutaneously at an initial dose of 320 mg, and the weekly dose recommended is 160 mg. In children >11 years and adolescents the dose is 4.4 mg/kg (maximal dose 320 mg) with subsequent doses 2.2 mg/kg (maximal dose 160 mg) once a week subcutaneously. The most common adverse events during the rilonacept treatment are local reactions in the injection site, respiratory, urinary tract infections and headaches, neutropenia, elevated liver transaminases and triglycerides, and creatine phosphokinase in laboratory tests (Sundy et al., 2014; Soriano et al., 2020).

In one clinical trial, rilonacept was effective in patients with FMF, resulting in a reduction in attack frequency (Hashkes et al., 2012). It also showed positive results and a good safety profile in patients with CAPS (Hoffman et al., 2012).

Rilonacept is also considered effective in Schnitzler syndrome resulting in rapid response with reduction of symptoms and markers of inflammation (Gusdorf and Lipsker, 2017).

TNF blockers have been used in monogenic AIDs, but in general, their effect was worse than IL-1 blockers. There are four essential drugs in this group:

- Etanercept (a dimeric human TNF receptor p75-Fc fusion protein),
- Infliximab (a chimeric monoclonal antibody against TNF- α),
- Adalimumab (a fully human monoclonal antibody against TNF- α)
- Golimumab (recombinant human IgG1/kappa monoclonal antibody against TNF- α).

The experience with anti-TNF drugs in monogenic autoinflammatory disorders remains unclear. Thus neither FDA nor EMA approves its use in these diseases. TNF blockers are commonly used (and approved by FDA and EMA) in the treatment of juvenile idiopathic arthritis, rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, and plaque psoriasis, Crohn's disease, ulcerative colitis, and non-infectious uveitis (Soriano et al., 2020).

The experience with the use of TNF blockers in FMF is limited. There are small groups of patients with concomitant conditions treated with one of the anti-TNF drugs with a good response, confirmed in Eurofever registry data (Ozgocmen and Akgul, 2011, Ter Haar et al., 2013). Moreover, these drugs seem to be more beneficial in patients with predominant arthritis (Ter Haar et al., 2013). The EULAR guidelines suggest that TNF blockers may be used in colchicine-resistant FMF, especially in those with articular involvement (Ozen et al., 2016).

In TRAPS, etanercept was reported to reduce the number of attacks and prevent them and reduce the dose of glucocorticoids necessary to maintain remission. Unfortunately, after about 3.3 years, it is common to discontinue the therapy due to lack of efficacy (Bulua et al., 2012; Ter Haar et al., 2013). Etanercept is still recommended in some of these patients but with additional information in the consensus that the effect may decline over time (Ter Haar et al., 2015). In the Euro fever registry, TRAPS patients treated with etanercept responded to the treatment in 88% of cases, with complete response in 26% (Ter Haar et al., 2013). Infliximab and adalimumab are not used in TRAPS patients due to severe paradoxical reactions (hyperinflammatory response) (Soriano et al., 2020).

Anti-TNF agents are used in Blau syndrome, alone or in combination with glucocorticosteroids or methotrexate. Early introduction of biological treatment was crucial to prevent permanent destruction of involved joints and vision loss/impairment (Matsuda et al., 2020). Successful treatment with TNF blockers was observed in patients with pyogenic arthritis, pyoderma gangrenosum, and acne syndrome (PAPA) (Tofteland and Shaver, 2010).

The spectacular response to anti-TNF agents was described in otulipenia, suggesting a potentially effective treatment for these patients (Damgaard, 2016).

Etanercept was the most effective treatment in patients with a deficiency of adenosine deaminase 2 (DADA) (Navon Elkan, 2014).

The consensus treatment plans for Chronic Non-Bacterial Osteomyelitis (CNO) proposed by Zhao et al. in 2018 included the use of TNF blockers for the patients who did not respond to NSAIDs or have active spinal lesions (Zhao et al., 2018).

Infliximab and adalimumab were shown effective in Behcet disease, mainly in large artery disease and symptoms from the gastrointestinal tract (Hatemi et al., 2018).

Anti-interleukin-6 agents

Tocilizumab is a humanized monoclonal anti-IL-6 receptor antibody. Its use has been approved for the treatment of rheumatoid arthritis, juvenile idiopathic arthritis, giant cell arteritis, and chimeric antigen receptor T (CAR-T) cell-induced severe cytokine release syndrome. The experience on tocilizumab efficacy and safety in monogenic AIDs is still inadequate. Thus it is not registered for the treatment of any of these diseases (Soriano, 2020).

There were few single cases of patients with colchicine-resistant FMF treated with tocilizumab. It has shown reasonable control of the disease flares. In patients with secondary amyloidosis and proteinuria, improvement was achieved in 75% of them (Ugurlu et al., 2017). There are few cases of tocilizumab use in TRAPS and HIDS/MKD resistant to anti-IL-1 or anti-TNF agents in the literature. No effect was achieved in patients with CAPS. There is no evidence of the use of tocilizumab in PFAPA patients (Soriano et al., 2020). In proteasome-associated autoinflammatory syndrome, anti-IL-6 therapy decreased CRP levels and normalized IL-6 responsive genes, but the effect was minor or transient (McDermott, 2015).

JAK inhibitors

JAK (Janus kinase) inhibitors block the induction of IFN-stimulated genes via suppressing the phosphorylation of the transcription factor STAT-1. This group represents tofacitinib, baricitinib, and ruxolitinib registered to treat rheumatoid arthritis, psoriatic arthritis, ulcerative colitis, myelofibrosis, polycythemia vera, and steroid-refractory GvHD.

JAK inhibitors showed positive effects in interferonopathies, for example, chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature/proteasome-associated inflammatory syndrome, STING-associated vasculopathy with onset in infancy, familial chilblain lupus, and Aicardi-Goutières syndrome (Soriano et al., 2020).

Other drugs

A small data in the Eurofever registry describes the use of such drugs as isotretinoin or cimetidine, administered in sporadic cases combined with biologic agents (Ter Haar et al., 2013). Rigante et al. also mentioned bisphosphonates, azathioprine, methotrexate, MALT-1 inhibitors, iron supplements (Rigante, 2017). As mentioned in previous paragraphs, the evidence for its efficacy and safety in AID is limited to use in single cases, and the precise guidelines are missing as autoinflammatory disorders are considered rare.

Thalidomide

Thalidomide has an anti-inflammatory effect through inhibition of TNF- α and IFN- γ production, angiogenesis, and leukocyte chemotaxis. Treatment of AID is based on a few case reports and series. It did not show efficacy or benefit in patients with FMF and HIDS/MKD (Soriano et al., 2020). Tacrolimus has been used in pyogenic arthritis, pyoderma gangrenosum, and acne syndrome (PAPA) with variable efficacy (Soriano et al., 2020). The effectiveness of tacrolimus was observed in the treatment of cherubism (Kadlub et al., 2015).

Dapsone

Dapsone is an antibacterial drug from the sulfonamide group. Its anti-inflammatory properties are based on inhibition of some neutrophil functions and blockade of the effects of prostaglandins and leukotrienes. In AIDs, dapsone was proved effective in a group of patients with FMF—the attacks were controlled in 50% of them. The conclusion was that dapsone might be used as an alternative therapy in FMF cases nonresponding to first-line treatment (Salehzadeh et al., 2012).

Surgery

Tonsillectomy is considered a successful treatment of PFAPA syndrome, which can result in complete regression of symptoms. The data which supports this statement comes from two small clinical trials, and the evidence is moderate certainty (Burton et al., 2019). Peridis et al. conducted a meta-analysis that did not show the difference in treatment outcome between surgery or glucocorticoids in PFAPA treatment. It is not clear if additional adenotomy conducted with tonsillectomy adds an extra benefit to this type of treatment (Gaggiano et al., 2019).

INDEX

This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization, and it is arranged in set-out style, with a maximum of four levels of heading. Location references refer to the volume number, in bold, followed by the page number. Page numbers suffixed by *f*, *t* and *b* refers to figures, tables and boxes terms respectively. *vs.* indicates a comparison.

overview, 2:1033–1035
Trombiculidae (*see* *Trombiculidae*)
- Chikungunya virus (CHIKV), 2:103–104, 4:471
- Childhood vaccinations and schistosomiasis, 3:67
- Chilomastix mesnili*, 3:183
- Chimeric antigen receptor (CAR) T cell therapy, 1:288, 4:129, 4:489, 4:772
- Chimpanzee Coryza agent (CCA), 2:79
- Chinese ink and nigrosine, 4:37
- Chlamydia* (*Chlamydophila*), 3:399–400
antibiotics for, 1:747*t*
antigen detection, 1:746
cell culture method, 1:746, 1:746*t*
characteristics, 1:743
conjunctivitis, 3:207
developmental cycle, 1:744*f*
diagnosis, 1:745–746
epidemiology, 1:744–745
molecular detection, 1:745
pathogenesis, 1:744–745
serological diagnosis, 1:746
taxonomy, 1:743
treatment, 1:746
- Chlamydia abortus*, 1:745
- Chlamydia felis*, 1:745
- Chlamydia pneumophila* infections, 1:745
- Chlamydia psittaci*, 1:745
- Chlamydia trachomatis*, 3:207–208, 3:399, 4:87, 4:87*f*, 4:316
antibiotic regimes for, 1:747*t*
eye infection, 1:744
genital infection, 1:744–745
- Chloramines, 4:633
- Chloramphenicol, 4:502
- Chlorazul E, 4:36
- Chlorhexidine, 3:250–251, 3:383
- Chlorhexidine gluconate, 3:383
- Chlorine dioxide, 4:633
- Chlorine lactophenol wet microscopic preparation
spores in hair, 3:417*f*
spores in scarification of skin, 3:418*f*
- Cholangiocarcinoma (CCA), 2:439, 2:441–443, 2:445
- Cholera, 1:637
accessory enterotoxin, 1:639
prophylaxis, 4:536–540*t*
toxin, 1:638
- Chordopoxvirinae* (ChPV), 2:146
- Chorioamnionitis, 3:341
- Chorionic villus sampling (CVS), 4:279
- Choroidal neovascularisation (CNV), 3:241
- Choroidal tubercle, 3:211
- Choroidal tuberculoma, 3:211
- Chromatid break, 4:282, 4:282*f*
- Chromatid gap, 4:282, 4:282*f*
- Chromatography, 4:307
- Chromosome fragility index (CFI), 4:281
- Chromosomes, 1:483
aberrations, 4:283, 4:283*f*
staining of, 4:280–281
- Chronic active EBV, 2:43
- Chronic cavity pulmonary histoplasmosis, 3:21
- Chronic conjunctivitis, 1:744
- Chronic graft-versus-host disease (GVHD), 3:581
- Chronic granulomatous disease (CGD), 3:503–504, 4:14, 4:486
- Chronic HBV
chronic hepatitis, 2:114
diagnostic tests, 2:116
immune tolerance, 2:115
inactive carriers, 2:114
laboratory diagnosis, 2:115
occult hepatitis, 2:115
serologic markers in, 2:115*f*
- Chronic hyperplastic candidiasis (CHC), 3:375, 3:375–376*f*
- Chronic infectious mononucleosis, 2:43
- Chronic inflammation, 3:349

- Chronic inflammatory demyelinating polyneuropathy (CIDP), 4:718
- Chronic lymphocytic leukemia (CLL), 4:716
- Chronic mucocutaneous candidiasis (CMC), 3:377, 3:564, 4:169
- Chronic obstructive pulmonary disease (COPD), 1:666, 3:21
- Chronic periodontitis, 3:350
- Chronic respiratory tract infections, 1:646–647
- Chronic suppurative otitis media (CSOM), 3:259
- Chrysops* sp., 2:886–887, 2:889–892, 2:891f
- C. callidus*, 2:889
- C. centurionis*, 2:889
- C. dimidiata*, 2:889
- C. distinctipennis*, 2:889
- C. langi*, 2:889
- C. silacea*, 2:889
- C. zahrai*, 2:889
- Churg-Strauss syndrome, 4:10t
- Cibarium, 2:820
- Cimex hemipterus*, 2:971, 2:974, 2:977–978
- Cimex lectularius*, 2:971–972, 2:973f, 2:974, 2:976–977
- Cimicida
- biology, 2:972–974
- control, 2:977–978
- ecology, 2:972–974
- epidemiology, 2:974–977
- medical importance, 2:971–972
- overview, 2:971
- C1 inhibition, 1:155
- CIN2 lesions, 2:92
- Ciprofloxacin, 1:548, 1:701, 4:502, 4:615t, 4:616
- Circulating anodic antigen (CAA), 2:672
- Circulating cathodic antigen (CCA), 2:672
- Circulating immune complexes, 4:250, 4:250f
- Circulating vaccine-derived polio virus (cVDPV), 4:472–473
- Cis-acting replication element (cre), 2:175
- Citric acid cycle, 1:368
- Citrobacter amalonaticus*, 1:632
- Citrobacter freundii*, 1:632
- Citronellal, 2:1059
- CL. *See* Cutaneous leishmaniasis (CL)
- Clades, 2:68
- Cladophialophora bantiana*, 3:315
- Clarithromycin, 4:501
- Classical pathway (CP), 1:148–150, 1:239
- amplification, 1:152
- deficiencies, 3:558
- Classical swine fever (CSF), 2:108
- Class 1 integrins, 4:313, 4:313f
- Class switch recombination (CSR), 3:489, 4:111, 4:715
- CLEC9A, 1:110–111, 1:114, 1:116
- Clindamycin, 1:506, 1:625t
- Clinical hosts, 4:362
- Clinical Laboratory Improvement Amendments (CLIA) act, 4:21, 4:451
- Clinical Laboratory Standards Institute (CLSI), 1:677
- Clonal complex 17 (CC-17), 4:316–317
- Clonal expansion, 1:58
- Clonorchiasis, 3:194
- Clonorchis sinensis*, 3:194
- clinical manifestations, 2:442–443
- diagnosis, 2:445
- enzyme linked immunosorbent assay (ELISA), 2:445
- human treatment, 2:445
- immune response, 2:443
- life cycle, 2:439–441
- from liver fluke infections to cancer, 2:442
- overview, 2:438–439
- pathogenesis, 2:441
- Clostridia, 1:342, 3:74
- Clostridium* spp., 1:616
- C. difficile*, 1:623–624, 1:624f, 3:78
- C. perfringens*, 3:74
- Clotrimazole, for rhino-orbital-cerebral zygomycosis (ROCZ), 3:236
- Cloxacillin, 4:495
- CLRs. *See* C-type lectin receptors (CLRs)
- Clustered regularly interspaced short palindromic repeats (CRISPR), 1:222, 4:772–773
- Cluster of differentiation, 4:110
- CMC. *See* Chronic mucocutaneous candidiasis (CMC)
- CMRL medium, 4:95
- CMV. *See* Cytomegalovirus (CMV)
- Cnephia pecuarum*, 2:877
- CNS. *See* Central nervous system (CNS)
- Coagulase negative staphylococci (CoNS)
- clinical manifestations, 1:502–503
- infections, 1:507
- Coagulation factor XII (FXII)-associated autoinflammatory disease, 3:548
- Coagulation system cross-talk, 1:161
- Coatomer subunit α (COPA) syndrome, 3:545–546
- Coat proteins, 2:165–167
- Cocci
- gram-negative anaerobic, 1:615t, 1:617
- gram-positive anaerobic, 1:615t, 1:617
- Coccidia, 2:463, 2:466–467
- Coccidioides* spp., 3:315
- Coccidioidomycosis, 3:22, 3:315, 3:332, 3:378–379
- antibody detection, in host, 4:51–52
- clinical manifestations, 3:22
- etiological diagnosis, 3:22
- fungal antigens, detection of, 4:54
- placenta and fetus infections, 3:343
- treatment, 3:22
- Cochliomyia hominivorax*, 3:280f
- Codeine sulfate, 2:47
- Cofactor activity, 1:155
- Cognitive impairment, 3:307
- Cohn's fractionation, 4:713
- Co-infections with schistosomiasis, 3:65–67
- Colchicine, 4:794, 4:843–846
- Cold sores, 1:338
- Colistimethate, 4:499
- Colistin, 4:647
- Collapsing focal segmental glomerulosclerosis (cFSGS), 3:40
- Colonization, 4:663t, 4:666
- of bacteria, 3:289–290
- of fungi, 3:313
- mechanisms in intestinal tract, 3:79–80
- Colony biofilm model (CBM), 4:409, 4:409f
- Colony counting methods, 1:327
- Colony forming units (CFUs), 1:327, 4:85, 4:647
- Combined immune deficiencies (CID), 4:715
- DNA repair defects, 3:470–472
- syndromic features, genetic and immunologic defects, 3:466–469t
- Commensal bacteria, 1:348
- Common in fungal extracellular membrane (CFEM), 1:384
- Common non-sporicidal disinfectants, 4:632
- Common variable immunodeficiency (CVID), 3:485–488, 4:486–487, 4:715, 4:799–801, 4:803
- clinical manifestations, 3:487–488
- diagnosis, 3:488
- pathogenesis, 3:485–487
- prognosis, 3:488
- treatment, 3:488
- Community-acquired pneumonia (CAP), 1:520–521
- Community-acquired respiratory distress syndrome (CARDS), 1:732
- Community state types (CSTs), 2:758, 4:663t, 4:667
- Competitive ELISA, 4:5f, 4:6
- Complementary-determining region (CDR), 4:741
- Complement fixation test (CFT), 1:681, 3:332, 4:4, 4:102–103
- Complement-independent manner, C3 and C5 in, 1:154
- Complement proteins (CP), 1:161–162
- deficiency in, 1:161
- hemolytic assays, 1:165
- Complement regulation deficiencies, 3:560
- Complement regulatory proteins, 1:156t
- deficiency in, 1:162–163
- function of, 1:157f
- Complement system, 1:3–4, 1:102, 1:103f, 1:104, 1:238–239, 2:5, 3:557–558, 4:161, 4:162f
- activation pathways, 3:557, 3:557f
- alternative pathway (AP), 1:151–154, 1:152f
- analysis, 4:163, 4:284–285
- assays, 4:163
- cell surface expression, 4:165
- complement system, 4:161, 4:162f
- detection of autoantibodies, 4:165
- diseases, 4:161–163, 4:162t
- measuring functional activity of single components, 4:164
- quantification of activation products, 4:164–165
- quantification of individual complement components, 4:164
- sample collection, 4:163

- standardization and quality control, 4:165
- tissue deposition, 4:165
- total complement function, 4:163–164, 4:164f
- biomedical relevance, 1:147
- C3 and C5 in complement-independent manner, 1:154
- classical pathway (CP), 1:148–150
- control family, 2:168
- deficiencies, 3:558–561
- of alternative pathway, 3:558
 - C3 deficiency, 3:558–559
 - of classical pathway, 3:558
 - laboratory diagnosis of, 3:560–561
 - lectin pathway, 3:559
 - regulation, 3:560
 - of terminal components, 3:559
 - treatment, 3:561
- dependent assays, 4:102–103
- in disease, 1:161–164
- complement-mediated pathology, 1:163–164

 keratitis, 3:224–225
 PEP dosages in people with normal renal function, 4:620*t*
 solid organ transplant recipients, 4:610
Variella, 1:338
Variola virus (VARV), 2:146–147
Vascular endothelial cells, 1:236
Vasculitis, 3:305
V-ATPase proteins, 1:104
Vaxchora[®], 1:642
VC[®] Rapid Dipstick, 4:24
Vectorborne viral transmission, 2:10
Vector control, 2:846–847
Vectored vaccine, 2:57
Vectors, 2:10, 2:101
Vehicleborne viral transmission, 2:10
Venereal Disease Research Laboratory (VDRL) test, 1:726
Venezuelan equine encephalitis virus complex (VEEV), 2:103
Ventilator-associated pneumonia, 1:646
Verotoxigenic *Escherichia coli* (VTEC), 4:315, 4:315*f*
Vertical transmission, virus, 2:10
Very early onset inflammatory bowel disease (VEO-IBD), 3:515
Vesicular stomatitis, 2:874, 2:880
Vesicular stomatitis virus (VSV), 2:298, 2:881
Viable cell counting, 4:90–91, 4:91*f*
Vibativ[®] (telavancin), 4:559–561*t*, 4:566*f*, 4:568
Vibrio fetus, 1:686
Vibrio pathogenicity island (VPI), 1:638
Vibrio spp. 3:76
 clinical illnesses, 1:640
 culture, 1:641
 diagnosis, 1:641
 epidemiology, 1:639–640
 immunity, 1:638–639
 microbiology, 1:637, 1:638*f*
 microscopy, 1:641
 nucleic acid amplification test (NAAT), 1:641
 pathogenesis, 1:638–639
 treatment, prevention and control, 1:641–642
 V. cholerae, 1:640, 3:76
 V. parahaemolyticus, 1:640
 V. vulnificus, 1:640
Vincent angina/trench mouth, 1:620
Viral avoidance, of immune response
 antigenic variation (antibody escape), 1:437–438
 hiding within immune cells, 1:439
 IFN response, modulation of, 1:439
 interference of viral antigen presentation, on MHC class I molecules, 1:437
 PRR signalling, modulation of, 1:438
 viral latency, 1:439
Viral-bacterial interactions, in AOM, 3:265–266
Viral clearance, 2:94–95
Viral cultures, 2:74
Viral disease
 acquired immunodeficiency syndrome, 2:905
 bovine leukosis, 2:905
 equine infectious anemia (EIA), 2:905
 lumpy skin disease (LSD), 2:905
 porcine reproductive and respiratory syndrome (PRRS), 2:905
 rift valley fever, 2:905
 West Nile encephalitis, 2:905
Viral envelope, 2:293–294
Viral genome organization, 2:174
Viral glycoprotein, 2:54
Viral hepatitis, 2:113
Viral-induced glomerulonephritis, 3:39–40
Viral infection, 1:121–122, 1:198–199, 2:8–9, 3:396, 4:718
 hepatitis B virus (HBV), 3:397–398
 herpes simplex virus (HSV), 3:396–397
 human immunodeficiency virus (HIV), 3:396
 human papillomaviruses (HPV), 3:397
Viral inhibition assay, 4:127
Viral load, 2:126, 2:129
Viral membrane assembly proteins (VMAPs), 2:150
Viral ocular infections, 3:219–234, 3:219–222
Viral proteins (VP), 2:68–70, 2:165–167
Viral recognition, innate immunity
 C-type lectin receptors (CLRs), 1:432
 cytosolic DNA sensors, 1:433
 downstream signalling, after PRR activation, 1:433–434
 interferon (IFN) pathway, 1:434
 mitogen-activated protein kinase (MAPK) pathway, 1:434
 NK- κ pathways, 1:434
 nucleotide-binding oligomerization domain-like receptors (NLRs), 1:432–433
 pattern recognition receptors (PRRs), 1:431–433, 1:433*f*
 retinoic acid inducible gene-I (RIG-I) like receptors (RLRs), 1:432
 toll like receptors (TLRs), 1:431–432
Viral replication, 2:7–8, 2:194–196
Viral RNA, replication of, 2:160
Viral skin diseases, 1:338
Viral transmission, 2:9–10
Viral vaccines, 4:546–547, 4:547*t*
Viral vector-based gene therapy, 4:765–768, 4:767*t*, 4:769*t*
Viridans group, 1:534
Viron, 2:1, 2:106, 2:174
Virology, 2:123–126, 2:124*f*
Virome, 1:317
Virulence factors, 1:357–361, 1:493, 1:581, 1:664–665, 4:315–316
 in bacteria, 1:493
 specific, 1:494
Virus culture media, 4:95
 antibiotics, 4:96
 cultivation of viruses, 4:96–98, 4:97*f*
 isolation of viruses, 4:96
 optimum pH, 4:96
 osmolality, 4:96
 serum, 4:96
Virus discovery based on cDNA-AFLP (VIDISCA) method, 4:467, 4:470
Viruses, 2:1, 3:363–364
 adaptive immune cells, in antiviral response, 1:435–437
 archival samples, 4:399
 classification, 2:5–7, 2:5–6*f*
 common techniques used in molecular pathology, 4:400–403, 4:400*f*
 diversity, 2:2
 electron microscopy, 2:2*f*
 formalin-fixed paraffin embedded samples, 4:399
 frozen samples, 4:399
 genomic changes, 2:4, 2:4*f*
 immune system, 1:429
 immunohistochemistry (IHC), 4:400–401
 innate immune cells, in antiviral response, 1:434–435
 innate immunity, 1:429–434
 in situ hybridization (ISH), 4:401–402, 4:404*t*
 with Laelapidae and Dermanyssidae, 2:1025*t*
 liberation, 2:176
 multiplex-staining, 4:403, 4:404*t*
 origin, 2:2–3
 polymerase chain reaction (PCR), 4:402–403, 4:404*t*
 release, 2:196–197
 replication cycle, 2:7–8
 structure and anatomy, 2:3–4
 viral avoidance, 1:437–439
Virus-first theory, 2:2
Virus-like particles (VLPs), 2:92, 2:95–96
Virus neutralization test (VNT), 4:100
Visceral larva migrans, 3:29–30
Visceral leishmaniasis (VL), 2:626–627, 3:145, 3:188–189, 4:514
 diagnosis, 2:632
 drugs and treatment schedules, 2:634*t*
 in HIV infection, 2:627–628
 in other immunocompromised patients, 2:628–629
Visible light scatter, 4:106
Vitamin(s), 4:780–781
Vitamin A, 4:780
Vitamin B, 4:780

Vitamin C, 4:780–781
 Vitamin D, 4:781
 Vitamin E, 4:781
 Vitek 2, 4:325
 VITEK[®] MS system, 4:28
 Vitrectomy, exogenous endophthalmitis, 3:244
 Viviparity, 2:844
 VLA2001 vaccine, 1:187
 VLPs. *See* Virus-like particles (VLPs)
 Voriconazole
 aspergillosis, 3:20, 3:237, 3:331
 coccidioidomycosis, 3:22
 exogenous endophthalmitis, 3:244
 keratitis, 3:240
 rhino-orbital-cerebral zygomycosis (ROCZ), 3:236
 Vulvovaginal candidiasis (VVC), 2:319–321, 3:55–56, 3:56*t*
 VVC. *See* Vulvovaginal candidiasis (VVC)
 VZV. *See* Varicella-zoster virus (VZV)

W

Wagatsuma-agar, 1:639
 Waldenstrom macroglobulinemia, 4:249
 Wall teichoic acids (WTA), 1:352
 Wart, 2:87
 Wash step, antibody phage display panning, 4:222
 Waterborne bacteria, 3:77
 Waterborne cryptosporidiosis, 2:451
 Wc-rBS (Dukoral[®]), 1:642
 WD repeat containing protein 1 (WDR1), 3:502, 3:540
 WEEV. *See* Western equine encephalitis virus (WEEV)
 Wegener's granulomatosis, 4:10*t*
 Western blotting (WB), 3:28, 4:7
 Western equine encephalitis virus (WEEV), 2:101–102
 West Nile encephalitis (WNE), 2:107, 2:905
 West Nile virus (WNV), 2:107, 4:471
 Wet mounts, 4:36
 WGS. *See* Whole genome sequencing (WGS)

WHIM syndrome-causing defects, 3:528
 clinical perspective, 3:528
 etiology, 3:528
 pathogenesis, 3:528
 Whipple's disease, 1:570, 3:214
 Whipworm infection, 3:185
 WHO. *See* World Health Organization (WHO)
 Whole blood, phagocyte activity in, 4:137
 Whole exome sequencing (WES), 4:801
 Whole genome sequencing (WGS), 1:468–469, 1:546, 4:29, 4:306, 4:336
 Whooping cough. *See* Pertussis
 Wigglesworthia spp. 2:840, 2:843–844
 Window period, 4:433–435, 4:439
 Wing primordia, 2:957
 Winter vomiting bug, 1:342
 Wiskott-Aldrich syndrome (WAS), 3:470, 3:503
 Wiskott-Aldrich syndrome protein (WASP), 3:539–540
 WNE. *See* West Nile encephalitis (WNE)
 WNV. *See* West Nile virus (WNV)
 Wolbachia, 2:603–604, 2:607, 2:610–614, 2:615*t*, 2:879, 4:519–520
 World Health Organization (WHO), 1:314, 4:287, 4:495
 Wuchereria bancrofti, 2:607–608, 2:609*f*, 2:610, 2:612, 2:614, 2:615*t*, 4:519–520

X

Xanthine derivatives, 3:602
 XC chemokines, 1:193
 XCR1, 1:110–111
 Xenleta[®] (lefamulin), 4:559–561*t*, 4:574*f*, 4:579
 Xenopsylla cheopis, 2:985*t*, 2:985*f*, 2:988, 2:989*f*
 Xenotropic MLV-related virus (XMRV), 4:474
 Xerava[®] (eravacycline), 4:559–561*t*, 4:574*f*, 4:576
 Xifaxan[®] (rifaximin), 4:559–561*t*, 4:564–565

X-linked agammaglobulinemia (XLA), 3:482–483
 X-linked lymphoproliferative disease, 2:45
 X-linked severe combined immunodeficiency (SCID-X1), 4:763–764
 Xpert MTB/RIF test, 4:304
 Xtoro[®] (finafloxacin), 4:559–561*t*, 4:566*f*, 4:572
 XTT staining assay, 4:416–417, 4:417*f*

Y

Yaws, 1:728
 Yeasts, 2:305, 3:108, 3:314, 4:44–49
 biochemical-physiological criteria, 4:46–49
 immunological criteria, 4:49
 and mold culture media, 4:94–95, 4:95*t*
 morphological criteria, 4:45–46
 Yellow fever virus (YFV), 2:2*f*, 2:106–107
 Yellow-white nodules, on umbilical cord, 3:341*f*
 Yersinia, 1:635
 Yersinia enterocolitica, 3:77

Z

Zaire ebolavirus, 2:294
 Zanamivir, 4:620
 Zeftera[®] (ceftobiprole medocartil), 4:567
 Zelonía australiensis, 2:881
 Zemdri[®] (plazomicin), 4:559–561*t*, 4:574*f*, 4:576
 Zerbaxa[®] (ceftolozane/tazobactam), 4:559–561*t*, 4:566*f*, 4:572–573
 Ziehl-Neelsen staining, 4:38, 4:39*f*
 Zika virus, 4:471–472
 Zinc, 1:384–385, 4:780
 Zoonosis, 2:666, 2:947, 2:949, 2:954
 Z rings, 1:330–332, 1:331*t*
 Zygomycosis, 3:235, 3:344
 Zymosan, 4:134
 Zyvox[®] (linezolid), 4:558, 4:559–561*t*

ENCYCLOPEDIA OF INFECTION AND IMMUNITY

VOLUME 4

Editor in Chief

Nima Rezaei

- Section 1. The Immune System, edited by Nima Rezaei
- Section 2. Pathogens and Immunity, edited by Rowena Jenkins
- Section 3. Bacteria, edited by Fernando Cobo
- Section 4. Viruses, edited by Nima Rezaei
- Section 5. Fungi, Protozoan Parasites, and Helminths, edited by Fanny Lanternier and Fabrizio Bruschi
- Section 6. Insect and Mites, edited by Giovanni Benelli
- Section 7. Clinical Infectious Disease, edited by Federico Iovino
- Section 8. Clinical Immunology, edited by Hans D. Ochs and Nima Rezaei
- Section 9. Laboratory Tests, edited by Nima Rezaei
- Section 10. Treatment Protocols, edited by Nima Rezaei
